Kents mechanical..

PREFACE

Much of the preliminary planning for this new edition of *Kent's Mechanical Engineers' Handbook* was done by Robert Kent prior to his untimely death in 1947. More than half of the contributors had been given their assignments and were already at work on their sections. The present editor has kept in constant view the objectives that guided both William Kent and Robert Kent in preparing the previous eleven editions of this Handbook. However, advantage has been taken of the latitude permitted in the selection of the remaining subjects and their authors to effect a slight change in emphasis, which is symbolized by the adoption of the subtitle *Design and Production*, in place of the previous *Design, Shop Practice*, for this volume of the Handbook.

The earlier title recognized the tie-in between the design engineering department and the shop. The new one underscores the fact that design and production are becoming recognized as simply two phases of a single activity—the engineering of a product from the inception of an idea to the completion of the finished article at an economical cost.

This volume is directed primarily toward the engineers who *design* and *manufacture* machinery, appliances, mechanical equipment, and other engineered products. The twenty-eight sections into which the book has been rearranged may be classified broadly as: Selection of Materials (Sections 1 to 6); Design Principles (Sections 7 to 9); Design and Selection of Machine Components (Sections 10 to 18); Production Processes (Sections 19 to 25); Production Plant Equipment (Sections 26 and 27); and Mathematical Tables (Section 28).

The presentation of each subject attempts to give the engineer a quick grasp of the essentials of the field, together with pertinent technical data in condensed form. These data consist essentially of: basic principles; working formulas, charts, and tables; standard dimensions, proportions, and specifications; and illustrated discussions of typical equipment. References included in the text and at the ends of many of the chapters guide the reader to sources of more detailed information.

With minor exceptions, the book has been almost completely rewritten. New material, required by progress in many fields, has outweighed the obsolete material that has been discarded, resulting in a book more than three hundred pages longer than the previous edition. The ninety-two contributors have prepared material ranging in length from a few paragraphs to entire sections. In addition, many industrial concerns have furnished data and illustrations, either to the individual authors or to the editor directly, the sources being indicated in all cases.

The publishers and the editor take this occasion to acknowledge with appreciation the cooperation of the many individuals and organizations whose interest and help have made this volume possible.

Colin Carmichael

March 1950

ABSTRACT FROM PREFACE TO THE FIRST EDITION, 1895

More than twenty years ago the author began to follow the advice given by Nystrom: "Every engineer should make his own pocket-book, as he proceeds in study and practice, to suit his particular business." The manuscript pocket-book thus begun, however, soon gave place to more modern means for disposing of the accumulation of engineering facts and figures, viz., the index rerum, the scrap-book, the collection of indexed envelopes, portfolios and boxes, the card catalogue, etc. Four years ago, at the request of the publishers, the labor was begun of selecting from this accumulated mass such matter as pertained to mechanical engineering, and of condensing, digesting, and arranging it in form for publication. In addition to this, a careful examination was made of the transactions of engineering societies, and of the most important recent works on mechanical engineering in order to fill gaps that might be left in the original collection, and insure that no important facts had been overlooked.

Some ideas have been kept in mind during the preparation of the pocket-book that will, it is believed, cause it to differ from other works of its class. In the first place it was considered that the field of mechanical engineering was so great, and the literature of the subject so vast, that as little space as possible should be given to subjects which especially belong to civil engineering.

Another idea prominently kept in view by the author has been that he would not assume the position of an "authority" in giving rules and formulae for designing, but only that of compiler, giving not only the name of the originator of the rule, where it was known, but also the volume and page from which it was taken, so that its derivation may be traced when desired. When different formulae for the same problem have been found they have been given in contrast, and in many cases examples have been calculated by each to show the difference between them. In some cases these differences are quite remarkable. Occasionally the study of these differences has led to the author's devising a new formula, in which case the derivation of the formula is given.

Much attention has been paid to the abstracting of data of experiments from recent periodical literature, and numerous references to other data are given. In this respect the present work will be found to differ from other pocket-books.

William Kent

CONTENTS

(Detailed tables of contents are given at the beginning of each section. An alphabetical index appears after Section 28.)

SECTION 1. GENERAL PROPERTIES OF MATERIALS

General Properties of Metals and Alloys 1-02
The Application of Data on Strength of Metallic Materials 1-16
Hardness, Density, and Compressibility 1-24

SECTION 2. IRON AND STEEL

SECTION 3. CORROSION AND CORROSION RESISTANCE

Corrosion of Metals 3-02
Corrosion Resistance of Metals and Alloys 3-17

SECTION 4. NONFERROUS METALS AND ALLOYS

Aluminum and Its Alloys 4-02
Copper and Copper-base Alloys 4-23
Magnesium and Its Alloys 4-40
Nickel and Its Alloys 4-50
Zinc and Its Alloys 4-60
The Less Common Metals 4-67
Bearing Metals 4-73
Die-casting Alloys 4-78
Solders 4-84
High-temperature-resistant Alloys 4-85

SECTION 5. NONMETALLIC MATERIALS

Carbon and Graphite 5-02
Ceramics 5-09
Cork 5-16
Felt 5-18
Glass 5-25
Plastics 5-31
Refractories 5-46
Rubber and Rubber-like Resilient Materials 5-57
Silicones 5-69
Wood 5-73

SECTION 6. FABRICATED MATERIALS

SECTION 7. MECHANISM, MECHANICS, AND MACHINE ELEMENTS

Mechanism 7-02
Mechanics 7-18
Machine Elements 7-34

SECTION 8. STRENGTH OF MATERIALS

Static Stresses 8-02
Dynamic Stresses 8-37
Working Stresses 8-43
Testing of Materials 8-53

SECTION 9. VIBRATION AND NOISE CONTROL

Vibration 9-02
Vibration Prevention 9-08
Noise 9-24
Noise Prevention 9-26

SECTION 10. FASTENERS

Screws and Screw Fasteners 10-02
Rivets and Riveted Joints 10-58
Fasteners for Wood Joints 10-68

SECTION 11. MECHANICAL SPRINGS

SECTION 12. BEARINGS AND LUBRICATION

Classification of Bearings 12-02
The Loading and Friction of Bearings on Films of Lubricant 12-03
Lubricants 12-61
Rolling Bearings 12-66
Straight, Needle, and Tapered Roller Bearings 12-94

SECTION 13. MACHINE HYDRAULICS

SECTION 14. GEARING

SECTION 15. MECHANICAL POWER TRANSMISSION

Shafts, Keys, and Splines 15-02
Couplings 15-17
Clutches 15-31
Pulleys 15-39
Cone Pulleys 15-43
Belt Drives 15-44
Short-center Belt Drives 15-63
Chain Drives 15-68
Rope Driving 15-80
Friction Gearing 15-83
Variable-speed Drives 15-84
Hydraulic Torque Converters 15-97

SECTION 16. ELECTRIC MOTORS AND THEIR CONTROL

Electric Motors 16-10
Electric Motor Control 16-57

SECTION 17. CONTROL MECHANISMS

Automatic Regulators 17-02
Servomechanisms 17-15
Industrial Electronic Control 17-23
Brakes 17-37

SECTION 18. MACHINE COMPONENTS AND TESTING

Pressure Seals 18-02
Cottered Joints, Pin Joints, and Tapers 18-15
Machine-performance Testing 18-22
Dynamometers 18-28
Thermometers and Pyrometers 18-31
Calculating Devices 18-35

SECTION 19. METAL MOLDING AND CASTING PROCESSES

Iron and Steel Casting 19-02
Malleable Iron Castings 19-26
Copper-base Alloy Casting 19-32
Aluminum-alloy Casting 19-36

Magnesium-alloy Casting.............. 19-38
Zinc-alloy Casting.................... 19-39
Precision Investment Casting.......... 19-40
Powder Metallurgy.................... 19-45

SECTION 20. PLASTIC WORKING OF METALS

Forging.............................. 20-02
Stamping Processes.................. 20-15
Shot Peening........................ 20-40

SECTION 21. JOINING OF MATERIALS

Welding of Metals................... 21-02
Brazing............................. 21-12
Adhesives and Glues................. 21-20

SECTION 22. INDUSTRIAL HEATING PROCESSES

Industrial Furnaces................. 22-02
Industrial Electric Heating......... 22-15

SECTION 23. METAL-CUTTING PROCESSES

Single-point Metal-cutting Tools......... 23-03
Lathe Work.......................... 23-28
Planer Work......................... 23-38
Metal-working Shapers............... 23-43
Milling Machine Practice............ 23-46
Drills and Drilling................. 23-63
Abrasive Processes.................. 23-71
Broaching........................... 23 101
Metal Sawing........................ 23-108
Gear-cutting Processes.............. 23-112
Flame Cutting....................... 23-116

SECTION 24. DIMENSIONAL CONTROL

Specification of Dimensions and Tolerances........ 24-02
Dimensional Measurements............ 24-16
Measurement and Designation of Surface Quality........ 24-27
Statistical Quality Control......... 24-33

SECTION 25. WORKING OF NON-METALLIC MATERIALS

Woodworking......................... 25-02
Plastics Molding.................... 25-47

SECTION 26. MATERIALS HANDLING

Hoisting............................ 26-02
Handling Material in Bulk........... 26-09
Cranes and Derricks................. 26-15
Hoists.............................. 26-23
General Conveying and Elevating....... 26-30
Vehicles............................ 26-49

SECTION 27. PRODUCTION PLANT CONSTRUCTION AND EQUIPMENT

Building Construction............... 27-02
Illumination........................ 27-64
Safety Engineering.................. 27-79
Dust Collection..................... 27-90

GENERAL PROPERTIES OF METALS AND ALLOYS

By Norman B. Pilling

1. THE METALS

CLASSIFICATION. There are more than 90 chemical elements (Table 1), more than 70 of which are classified as metallic, 4 as metalloids, and 14 as nonmetallic. Of the metallic elements, some 20 or more lie in the groups of rare-earth and radioactive metals, which, because they are very scarce and difficult to separate, are chiefly of scientific interest only at the present time. The 4 metalloids are boron, carbon, phosphorus, and silicon. Although their chemical properties relate them to the nonmetallic elements, the metalloids form true alloys with many metals and are among the most useful metallurgical elements.

PROPERTIES. The metals owe their engineering importance to properties, especially combinations of properties, which they display either uniquely or in far greater intensity than other classes of materials. Among the distinctive properties of metals are their high conductivity for electricity and the facility with which they may be mixed, or alloyed, with each other to enhance some properties, or even to create new qualities not displayed by the component metals. The conservative employment of metals attaches great importance to the improvement and control of their properties.

The technologically interesting metallic and metalloidal elements, with the chief properties which have metallurgical significance, are listed in Table 3.

METALLIC ELEMENTS, METALS AND ALLOYS. Few metals indeed are ever seen in a state approaching complete purity. The term *metallic element* assumes such purity; the physical constants of the elements are expressed with such an implication or in relation to some stated degree of purity. Although all the metals that are sufficiently tractable to have importance can be prepared to a high degree of chemical purity provided sufficient effort is expended, the purity to which the metals are commonly refined is set by the requirements of their principal end uses, and to this their cost is to a considerable extent related. (See Table 2.)

By general usage, the term *metal* is employed in a generic sense, often referring both to simple metals as well as to metallic alloys. There can be no distinction between alloys and simple metals based upon order of purity; the word *alloy* implies a purposeful mixture.

2. STRUCTURE OF METALS AND ALLOYS

All substances whether solid, liquid, or gaseous, elemental or complex, are composed of atoms of the ninety-odd elements. The atom is not the most elementary particle of nature but has a complex internal structure which is frequently diagrammed as consisting of a central, electrically charged nuclear body surrounded by an atmosphere of oppositely charged particles of a different nature, the electrons. The arrangement of the elements in the periodic table parallels a systematic progression in the nucleus/electron pattern. The several distinctive properties of metals originate at different depths within the atomic structure. This is the field of atomic physics.

SIMPLE METALS. In general, metals in the gaseous and liquid states are characterized by absence of crystallinity. In the solid state, metals are almost completely crystalline, although little in their outward appearance suggests this. The evidence of crystallinity is complete, however, and is revealed by x-ray diffractive powers and by light reflective behavior of finely etched surfaces when suitably examined with a microscope. Crystalline texture is not necessarily combined with geometrically regular external form. This is because it generally happens that as metals solidify from the molten condition, a great multitude of crystals starts to form; these soon grow into each other and interfere with the further development of regular form. Metal crystals grow during solidification in skeleton shapes, as a series of geometrically related arms, branches, subbranches, etc., which interlace the liquid and finally trap the last drops to solidify in the interstices of this branching

Table 1. The Chemical Elements

(Data from *The Metals Handbook*, American Society for Metals, 1948. By permission.)

Element	Symbol	Atomic Number	Atomic Weight	Element	Symbol	Atomic Number	Atomic Weight
Actinium	Ac	89	227.05	Mercury	Hg	80	200.61
Aluminum	Al	13	26.97	Molybdenum	Mo	42	95.95

1. Designation based on the periodic table; elements with like designations are chemically similar and have other general resemblances.
2. Brinell hardness number, soft condition.
3. psi = pounds per square inch.
4. At 70 F ±.
5. Thermoelectric power relative to lead.
6. FC = face centered; BC = body centered; CP = close packed; D = diamond symmetry.
7. Å = Ångstrom unit = 10^{-8} cm.

system. Many of the qualities of metals and alloys are inherited from this mode of freezing. Evidences of their tree-like or dendritic texture are commonly seen in the microstructure of cast alloys. Geometrically shaped crystals are sometimes seen in metals condensed from vapor, and in the interior of large ingots from which the liquid contents have been suddenly emptied after partial freezing.

Crystalline Textures. The essence of crystalline texture is the arrangement of atoms on a precisely recurrent, regular three-dimensional pattern. For most metals, and the alloys derived from them, these patterns are rather simple. About 60% of the common metals crystallize in some cubic pattern, and 30% in some hexagonal pattern (Table 3.)

The three forms of crystalline pattern, or *space lattice*, most common to the metals are shown in Fig. 1. These three lattices develop directly from the geometry of layers of uniformly sized spheres arranged to achieve efficient packing.

The basic dimension of the lattice is the length of the sides of the unit cell, or *lattice constant*, which is expressed in Angstrom units (1 Å = 10^{-8} cm). Because atoms differ in size this dimension varies from one metal to another and ranges from about 2.9 to 6.2 Å. Lattices other than cubic have more than one lattice constant, depending on the symmetry of the unit cell.

The significant systems of crystallographic planes are those on which the atoms lie in greatest numbers. These planes play a part in plastic straining and brittle cleavage and often fix the pattern upon which precipitates form. The more important planes are shown upon which the slip mechanism operates in the three principal lattice types. (See Fig. 2.)

FIG. 2. Significant crystalline planes.

Grains and Grain Boundaries. It is unusual to encounter metals composed of only a single crystal; most metal parts are aggregates of crystals. In castings, i.e., metals that have merely solidified from the liquid state, the shape of the crystals, or *grains* as they are usually called, is irregular and almost never geometrically symmetrical. The grains differ randomly in relative orientation and for this reason can be separately distinguished. The grain size of castings is usually much larger than that of metals which have been annealed and recrystallized, and is determined by the number of points at which solidification independently starts. The formation of large grains in freezing is favored by slow, undisturbed cooling; on the other hand, turbulent motion and rapid extraction of heat at temperatures close to the freezing point diminish the grain size. Column-shaped grains result from unsymmetrical heat extraction, as against the walls of chill molds. Large ingots characteristically have a shell of columnar grains enclosing a central core of smaller, equiaxed grains.

Hot working, or annealing after cold working, results in recrystallization, whereby a new generation of grains comes into being. This process starts from many centers. The new grains enlarge by advancement of their boundaries in detail across old grains. The first result is a refinement in grain size, but prolonged overheating may lead to great coarseness in grain size.

Grain boundaries represent the surface along which the differently directed lattices of similar grains meet. In pure metals it is a tenuous zone in which the attractive forces of the adjacent crystals compete. The atoms in this zone are thought to be noncrystalline, and some qualities of polycrystalline metals harmonize with the supposition. At any rate, at ordinary temperatures grain boundaries are sources of strength, not weakness.

The grain structures of metals and alloys are revealed for study or inspection by the preparation of polished, cut sections which are lightly etched with slow-acting acid solutions. Many features become visible to the unaided eye and much is revealed by microscopic examination up to 1500 diameters enlargement. Crystalline textures are revealed and analyzed only through the diffraction of x-rays or other short radiations.

Allotropy. Some metals exist in more than one crystalline form, with each type of lattice stable over a definite temperature range (Table 4). These differing forms sometimes have widely different properties which may have great practical importance. For example, the two allotropic forms of iron have greatly different solubilities for carbon, making possible the development of hardening and heat treatment of steel. At the temperature of transformation from one allotropic phase to another, density, electrical, thermal, and other property changes may occur. The allotropes are designated by Greek letters.

Table 4. Allotropic Forms of the Metals

Metal	Allotropic Phase	Upper Temperature Limit of Stability, °F	Crystalline Form
Cobalt	Alpha	880	CP Hexagonal
	Beta	Melting point	FC Cubic
Iron	Alpha	1663	BC Cubic
	Gamma	2557	FC Cubic

Tin	Alpha	64	Tetrahedral cubic
	Beta	322	BC Tetragonal
	Gamma	Melting point	Hexagonal
Zirconium	Alpha	1584	CP Hexagonal
	Beta	Melting point	BC Cubic

ALLOYS. Two metals alloy if they melt together to form a homogeneous liquid. The solid alloy which freezes from it is crystalline and, like simple metals, consists usually of an aggregate of grains. These grains may be of several kinds, depending on the metal pair. (1) The grains may be homogeneous, the atoms of the two metals forming a single lattice similar to that of one of the metals, i.e., a *solid solution.* (2) The two metals may combine to form an *intermetallic compound* with an entirely new, and frequently complex, lattice structure. (3) The grains may be *composite*, as a physical mixture of two kinds of solid solution grains, a solid solution and an intermetallic compound, or two intermetallic compounds.

Alloying may also be accomplished at temperatures below the melting point by diffusion between contacting metals or reactive gases. Examples of these processes, which are slow, are carburization, cementation, and the bonding of electroplated layers. These methods of alloying are resorted to when fusion processes are not practical.

Two metals may show complete liquid insolubility when melted together, similar to oil and water. A limit of liquid solubility may be shown that is the maximum concentration dissolved before liquid separation occurs.

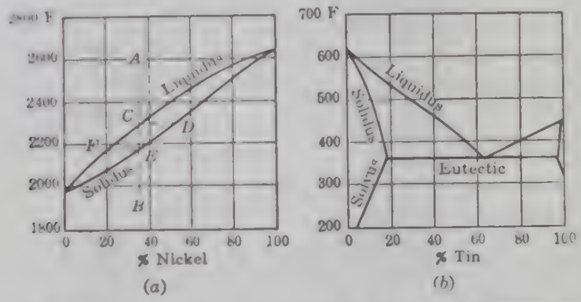
Solid Solubility. In the solid solution lattice, the atoms present in lesser proportion conform in position on the parent lattice but distort it to a degree depending on their relative lattice constants. Such accommodation is easiest when the lattice types are similar and when the size difference is less than 14%; greater distortions result in the formation or precipitation of other kinds of alloy crystal. Solid solubility is this limiting concentration.

The solid solubility of two metals may be complete, extending without break from one metal through all percentage ranges to the other. An example is nickel and copper. As nickel is increasingly added to copper, the lattice constant decreases continuously to that of nickel, and other properties such as electrical resistivity change continuously although not usually linearly. More frequently solid solubility is limited; the structure of a binary alloy of two metals, at a concentration which exceeds the solubility of either in the other, consists in a mixture of the two saturated solid solution phases, the proportions occurring being fixed by the respective solubilities.

Intermetallic compounds are the result of a more or less strong chemical union between two metals which differ considerably in position in the periodic table. They are generally hard and brittle, have complex lattice structures, and do not conform in combining proportions to the simple rules of chemical valence. Many dispersives in precipitation-hardened alloys are intermetallic compounds.

Equilibrium Diagrams. The complex relations of the structures of a two-component alloy series are described graphically and in quantitative detail by the equilibrium diagram of the series. This is a temperature-composition graph based on observed facts concordant with the phase rule of physical chemistry. Figures 3*a* and 3*b* are two of the simpler diagrams illustrating the types of information available for many binary alloy series. From such diagrams the melting temperatures and freezing ranges of the entire series may be read off; the course of freezing may be followed, and the related degrees of microsegregation may be estimated; eutectic ranges may be observed, and the existence of intermetallic compounds recognized; the extent of solid solubility and the way it changes with temperature may be noted.

Figure 3*a* shows two metals that form solid solutions in all proportions. The *liquidus* line describes the temperatures at which solidification normally begins upon cooling of the melted alloy. The *solidus* line represents the temperatures at which melting normally begins upon heating the solid alloy. These two curves are conjugate, and pairs of points on the two curves connected by a horizontal temperature line represent respectively the compositions of the liquid phase and the solid crystal which are in equilibrium with each other. In general, the composition of the first crystal to separate from the melt is not the same as the average composition of the melted alloy; it is richer in the metal of higher melting point. The vertical line *AB* illustrates the course of freezing of a molten 35% nickel alloy: *C*, initial freezing temperature; *D*, composition at heart of first dendritic crystal; *E*, temperature of completion of freezing; *F*, composition of last drops of liquid to freeze within the dendritic network. The temperature spread *CE* is the freezing range. The extremes of heterogeneity thus indicated would be found within alloy grains were it not that diffusion at high temperatures acts in an opposite manner and sets in as soon as liquid no longer is in contact. After the completion of freezing, prolonged heating at temperatures close to the freezing range may succeed in obtaining equalization of composition throughout the grains, or *homogenization*.



(*a*) (*b*)

FIG. 3. Equilibrium diagrams of simple two-component alloy series: (*a*) copper-nickel and (*b*) lead-tin series.

Figure 3*b* shows two metals that have only limited solid solubility for each other. It will be noted that the melting point of each metal is depressed by the other and the two liquidus curves ultimately intersect. The alloy (32% tin) corresponding in composition to point of intersection is the *eutectic alloy* and has the lowest melting point of the series; its melting point is the *eutectic temperature*. By following the course of freezing of an alloy richer in lead than the eutectic it will be seen that the liquid last to freeze is always of eutectic composition. The amount of eutectic thus present is in proportion to composition limits, e.g., 80% tin yields 50% eutectic. The eutectic alloy has a characteristic structure of finely laminated alternating plates of the two phases, suggesting a seesawing mode of freezing. The *solvus* line traces the changes of solid solubility with temperature.

It must be emphasized that the data of the equilibrium diagram are for conditions of complete structural stability, a matter seldom occurring in practical circumstances. Many transient or unstable structures of real importance can be systematized only in empirical *structural diagrams* for particular conditions of treatment.

Three-component, or ternary, alloys can be dealt with by three-dimensional models and by plane diagrams corresponding to sections through, or projections from, such models, but alloys containing more than three components are not readily diagrammed.

3. ALLOYING POWERS OF THE METALS

Although there are more than 70 metallic elements, most of the industrially important alloys are based on the 8 relatively cheap and abundant ones: iron, lead, copper, zinc, aluminum, nickel, tin, and magnesium. The more basic alloying properties of some of the metals with this group, and with the two principal precious metals which have industrial use, are in Table 5. If the data of Table 3 and Table 5 are combined, it is possible to sketch out the principal features of these binary alloys.

4. METALLIC PROPERTIES

Physical and mechanical properties are primarily established by the chemical composition and the structure; the latter is in turn a product of the working and thermal treatments which have been given. These properties may accordingly be controlled or varied within narrow or wide limits by suitable attention to these factors.

ELASTIC AND PLASTIC PROPERTIES. Of the many qualities of metals, perhaps the most significant to the engineer are the related properties of elasticity and plasticity. Upon plasticity depends the ability to shape metals into useful forms; elasticity governs their safe and economical use as load-bearing members.

Elasticity. A body is said to be elastic if, after change in shape when externally loaded, it returns to its original shape with removal of the load. The elastic limit is the maximum stress at which the body behaves elastically. The proportional limit is the stress at which strain ceases to be proportional to applied stress; it is practically equivalent to elastic limit. The modulus of elasticity, or stiffness, is the stress which would be required to produce 100% of strain if there were no limit to elasticity, e.g., to double the length of a bar if loaded by axial tension.

Plasticity, as applied to metals, is a term used to express an ability to be deformed beyond the range of elasticity without fracture, resulting in permanent change in shape. A diagrammatic stress-strain curve for a test bar in tension is shown in Fig. 4, in which the elastic and plastic ranges are distinguished. Characteristically, the ratio of plastic to elastic deformability in the useful metals is high, of the order of 100 : 1 or 1000 : 1. Interrupting the course of plastic straining, as shown by the dotted lines, results in an elastic recovery and an increase in the proportional limit on resumption of straining; this is an evidence of strain hardening. A fuller development of the external aspects of elastic and plastic behavior will be found in Section 8, Strength of Materials.

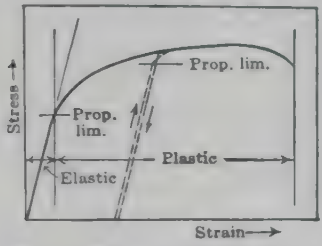

FIG. 4. Stress-strain curve for a test bar in tension, showing elastic and plastic ranges.

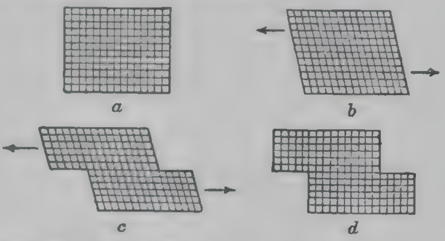

FIG. 5. Deformation of a cubic crystal lattice: (a) unstrained condition; (b) elastic deformation; (c) plastic deformation; (d) permanent set as result of slip.

Deformation in Single Metallic Crystals. A simplified two-dimensional representation of a cubic crystal lattice in an unstrained condition is represented by *a* in Fig. 5. If a shearing force is applied which is within the elastic range, the lattice is uniformly distorted as in *b*, the extent of the distortion being proportional to the applied force. When the force is removed, the lattice springs back to its original shape (*a*). However, when the force exceeds the elastic (or proportional) limit, a sudden change in the mode of deformation occurs; without further increase in the amount of elastic strain, the lattice shears along a crystallographic plane, or *slip plane;* one block of the lattice makes a long glide past the other and stops (*c*). Upon release of load, the lattice in the two displaced blocks resumes its original shape (*d*). If the applied force is continued, slip does not continue indefinitely along the original slip plane, which appears on the contrary to acquire resistance to further motion, but some parallel plane comes into action. Both the extent of slip per plane and the distance between active slip planes are large in comparison to the unit lattice dimensions. As slip shifts from one slip plane to another, progressively higher forces are required to accomplish it, i.e., the metal has been work hardened. At some stage, resistance to further slip along the primitive set of planes exceeds the resistance offered by some other set of differently directed slip planes, which then come into action. This process elaborates as plastic deformation progresses.

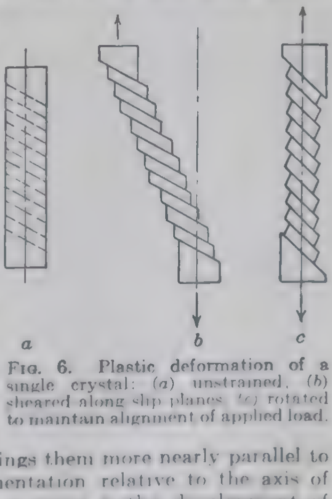

FIG. 6. Plastic deformation of a single crystal: (*a*) unstrained, (*b*) sheared along slip planes, (*c*) rotated to maintain alignment of applied load.

The slip mechanism outlined for a sample of lattice applies to the deformation behavior of a test bar made of a single grain. The simplest case is that of a hexagonally crystalline metal like zinc, in which there is but one principal set of slip planes. The basic effects are shown in Fig. 6. As the tensile force is exerted, blocks of the grain tend to shear, as in *b*, like the displacement of a stack of coins, at a stress which depends upon the angle between the slip planes and the direction of pull. Since external restraint compels the axis of the test bar to keep in line with the direction of pull, this accommodation occurs by an angular movement of the slip planes that brings them more nearly parallel to it (*c*). As this action occurs regardless of grain orientation relative to the axis of pull, it follows that an end result of severe plastic straining is the development of a preferred crystalline orientation, or fiber. As the single-grain test bar is further strained, its anisotropic qualities become apparent. An originally circular cross section becomes elliptical, and it finally draws down and breaks to a chisel-shaped edge.

These interesting effects are not always desirable; metals and alloys are generally in their most useful form if finely polycrystalline.

Deformation of Crystal Aggregates. Metal parts are normally an aggregate of a multitude of tiny, randomly positioned grains. The elastic and plastic behaviors of such an aggregate differ from that of a single grain for several reasons. (1) *Mutual reinforcement*, whereby those grains weakly positioned for slip are buttressed by more strongly positioned neighboring grains. (2) *Uniformity of properties*, since the strong directional qualities of the separate grains cancel out with their random placements. (3) *Grain boundary strength.* If insoluble components are not present, the grain boundary is an extremely thin zone in which the atoms are subject to the conflicting attractions for differently positioned lattices. At ordinary temperatures this zone is stronger than the rest of the grain; the path of fracture usually avoids grain boundaries. Increase in the intricacy of grain boundaries results in increase of hardness and related properties. (4) *Grain boundary segregations.* Many impurities or alloy components, if present as separate phases, show a tendency to collect along grain boundaries, intensifying the effects of their individual qualities.

Grain aggregates, when heavily cold worked, develop, for reasons explained in the preceding heading, a crystalline fiber or *preferred orientation* related to the principal direction of straining. Under some conditions of working and annealing this cold-worked fiber is transmitted to the recrystallized structure, forming an aggregate of grains regimented as to a lattice direction and showing some of the more annoying qualities of single grains.

INHERENT STRENGTH OF METALS. The stress required to rupture a metallic crystal in pure tension is not readily measurable, but calculations based on energetics disclose that the strength of metals as ordinarily measured is but a small fraction of their inherent strength. For copper, some significant comparisons are these:

Calculated tensile rupture stress	1,300,000 psi
Ultimate breaking strength	62,000 psi
Ultimate tensile strength	32,000 psi
Critical slip stress	150 psi

Similar relations are observed for other pure metals.

Inability to develop usefully the inherent strength of ductile metals results from (1) the relatively low slip shear strength; (2) the usual occurrence of fracture by degrees, starting at some internal focus and spreading. The local stress intensity at an internal discontinuity or at a focus of fracture may be many times greater than the average stress over the section.

Imperfections of many kinds may serve to localize and intensify stresses, such as flaws in the regularity of the crystal lattice, micro-cracks within a grain, shrinkage voids, nonmetallic inclusions, rough surfaces, and notches of all kinds. Many impurities owe their potency to a high degree of insolubility in the solid matrix coupled with high solubility in the fusion; this permits their freezing out relatively late in the solidification process, as concentrates or films between the grains, thus serving as effective internal notches. The great weakening effect of the graphite flakes in cast iron is an illustration.

Notches act not only as stress raisers but also as stress complicators, and frequently induce a degree of stress tri-axiality. The deeper the notch and the sharper the acuteness of its root, the more effective it is in this respect. A purely tri-axial stress could be relieved by no process of slip or shear, would result in fracture without deformation, and may occur internally in highly stressed parts. Notches are the great weakeners, and engineers do well to recognize their prevalence under many disguises.

EFFECT OF TEMPERATURE. Two effects of temperature on metals and alloys are distinguished: (1) temporary, in which properties characteristic of the temperature are acquired; and (2) permanent, in which changes occur which persist upon return of the metal to normal temperatures. At low, subatmospheric temperatures many steels and iron alloys become quite brittle, because of a change in the mode of deformation (cleavage). On the other hand, most nonferrous metals having crystal lattices of the face-centered cubic type, and their alloys as well as austenitic steels, remain tough at temperatures as low as that of boiling nitrogen (−320 F). At high temperatures, not only are metals subject to direct attack by atmospheric oxygen and by sulfurous and other combustion gases (scaling, sulfidation, and carburization) but they also take on temporary characteristics not readily disclosed by examination in the cold or by brief tests at temperature.

One common change in property is the reversal in strength at grain boundaries. At temperatures higher than the recrystallization temperature, the crystalline interior of the grain becomes stronger than the boundary, and metals broken at such temperatures show *intercrystalline fracture.* Metals and alloys intended for load-bearing service at such higher temperatures for this reason are preferred in a coarse-grained condition.

Flow under sustained loading, which is absent in elastic materials at ordinary temperatures, becomes the dominant characteristic at temperatures considerably below the recrystallization range. The evaluation of alloys for use in highly stressed parts operating at high temperatures is a difficult, lengthy, and expensive procedure, involving rates of creep, time to fracture, microstructural stability, and corrosion resistance, all as interrelated factors. Within or below the softening range, creep diminishes with time due to the accumulation of work-hardening effects, and this stage may persist for years. At higher temperatures or with higher stressing this stage may terminate with an unstable acceleration of creep, leading rapidly to fracture at stresses which may be as little as one-tenth the breaking stress in ordinarily rapid tension tests. As this termination with its serious consequences may be much delayed, creep tests are frequently required to approximate in length the expected life of the proposed equipment, such as several hundred hours for some types of aircraft engine or several years for heavy prime movers.

HARDENING OF METALS. All the effective means of hardening the metals accomplish it by greatly increasing the slip shear strength of the grain. These means are (1) work or deformation hardening, discussed under Article 5; (2) solid solution alloying; (3) formation of dispersed precipitates.

Solid Solution Hardening. Hardening by solid solution is accomplished by distortion of the crystalline lattice of the solvent metal by the solute atoms, with its resulting effect on the forces required to accomplish slip on warped or dimpled planes. The Rosenhain rule states that the specific hardening increment of a dissolved element is greater, the lower its maximum solubility in the matrix metal.

Precipitation Hardening. The hardening of metals by dispersed precipitates is widely practiced in current metallurgy. In principle it is applicable to any metal or kind of alloy and depends upon the development of a structure comprising, in the simplest case, grains of a single type in which are dispersed a multitude of extremely fine particles of some other metallic substance. The dispersed phase does not necessarily need to have a high intrinsic hardness. The hardness of its matrix results from a sort of mechanical interference with slip, the tiny particles in effect acting as "keys" against slip displacement. There is a most favorable size for dispersed particles to act in this manner, of the order of 10 to 100 times the lattice constant. Smaller or larger particles may have little hardening effect.

The basic requirements for obtaining such dispersed precipitates are (1) existence of a substance, usually an intermetallic compound, for which the matrix has a limited solid solubility, but which increases substantially in solubility with temperature; (2) provision of this substance in the alloy in an amount exceeding its lower limit of solubility; (3) establishment of a supersaturated solution by heating above the solubility-temperature limit, followed by rapid cooling; (4) reheating to a lower temperature at which the substance slowly separates from the matrix. If the temperature of step 4 is too high or the time allowed is too long, oversized and ineffective precipitates result. Details of the nature and necessary amount of precipitant and of heat treatment differ widely for various metal combinations.

Precipitation hardening has the advantage of being a reversible process; an alloy having this power may at will be put into a soft (solution treated) condition in which machining, forming, and other mechanical operations may easily be done. It may then be converted to the hard (precipitate) state for use, and the cycle repeated if desired.

5. TREATMENT OF METALS

The changes that can be evoked by mechanical work at various temperatures, by heat treatment for various purposes, and by altering the sequence with which a succession of these treatments is done afford ample opportunity for the skillful regulation and combination of properties.

HOT AND COLD WORKING. The deformation of metals or alloys in the cold, as by rolling, stamping, swaging, or drawing, results in an increase in hardness and tensile strength and a decrease in ductility. These changes are roughly proportional to the extent of deformation, usually expressed as the reduction in cross-sectional area or in thickness. The hardness and tensile strength of ductile alloys may in this way be increased two- or three-fold with, however, relatively much greater loss in ductility, to $^1/_{30}$ or $^1/_{50}$. Very heavy working develops fiber both as to included particles of impurities and as to grain structure, and a resulting directional difference in properties, as longitudinal versus transverse. Overworking results in edge cracking, internal bursts, and other permanent injuries. In general, a metal is cold worked at temperatures below the recrystallization range; it is hot worked at temperatures above it. Hot working, such as forging, hot rolling, and piercing, does not alter the mechanical properties as radically as cold working, since it is accompanied by simultaneous recrystallization and softening.

HEAT TREATMENT. Stress Relief. As a result of permanent deformation by cold working, internal elastic stresses remain which may cause distortions after cutting operations, lead to premature yielding, or even to fracture under corrosive attack. These stresses may be dissipated by heating to temperatures considerably below the softening range. The metal remains hard, but its elastic strength is improved. Residual tensile stresses are usually more detrimental than compressive stresses. Residual compressive stresses may be imparted to surfaces by an operation of blasting the surface, or peening, with fine steel shot; this operation may lead to improved performance of parts which fail by tensile fatigue, as in vibrational bending. (See Articles 10 to 12, Section 20.)

Annealing and Recrystallization. When metals which have been cold worked are heated, the first evidence of permanent change is the relief of internal stresses and a slow softening. Both occur before changes in microstructure are visible. The rate of softening of cold-worked copper (Fig. 7) depends upon the initial degree of cold work, and follows a logarithmic law that indicates steady but slow softening to ordinary temperatures. Other metals and alloys presumably behave similarly at different rates. This kind of softening must be taken into account in applications which rely upon the maintenance of properties over long periods of time.

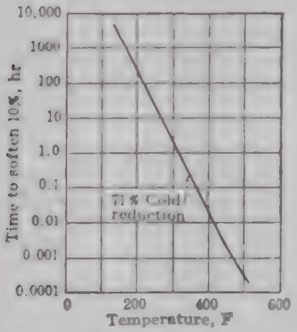

Fig. 7. Softening of hard rolled copper.

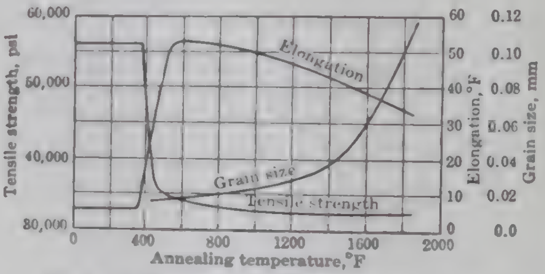

Fig. 8. Recrystallization of hard rolled copper.

At somewhat higher temperatures the distorted, elongated, worked grains may be seen to break down with the formation of a relatively few, tiny equi-axed grains. As time is further allowed, or temperature is increased, this recrystallization spreads throughout, resulting in a uniformly fine-grained structure, with the restoration of the characteristic softness and ductility of the unworked metal. The average grain size developed is principally related to the annealing temperature, although tending to be diminished by increasing degrees of cold work and by the presence of insoluble impurities. With increase in annealing temperature, grain size increases rapidly. An example of softening and recrystallization is given in Fig. 8. Recrystallization temperatures are subject to variation but, in the case of simple metals, they increase with rise in melting point; solid solution alloys have higher recrystallization temperatures than the parent metals; increase in amount of cold-work decreases moderately the temperature of recrystallization. (See Table 6.)

Table 6. Lowest Recrystallization Temperatures After Severe Cold Work of Metals of Commercial Purity

Metal	Temperature, °F	Metal	Temperature, °F	Metal	Temperature, °F
Tungsten	2200	Platinum	750	Magnesium	300
Molybdenum	1600	Copper	400	Zinc	70
Nickel	1100	Silver	400	Tin	64 *
Iron	850	Aluminum	300	Lead	Subatmospheric

* Transformation temperature to Alpha tin.

Thermal Hardening. The operation of heat-treating an alloy which is responsive to precipitate hardening is designed to accomplish the two steps of putting the precipitant into solution and then throwing it out of solution under critical temperature conditions.

Solution temperatures may vary widely, depending both on the basis metal and the nature and solubility of the precipitant (Table 7). In some cases, notably alloys preserving load-carrying ability at high temperatures, the strengthening precipitate not only must be stable at the temperature of use, but also must have its solubility limit at substantially higher temperatures. This may lead to solution temperatures approaching the melting range.

Table 7. Some Precipitate-hardening Alloy Systems

Predominant Metal in Matrix	Addition Elements	Precipitant Phase	Solution Temp., °F	Precipitating Temp., °F	Typical Hardness Range, BHN	
					Soft	Hard
Aluminum	Copper	$CuAl_2$	1000	300	62	105
	Magnesium, silicon	Mg_2Si	970	310	26	80
Copper	Beryllium	CuBe	1450	650	110	360
	Nickel, silicon	Ni_2Si	1500	500	90	170
	Nickel, tin	Ni_3Sn	1400	550	75	180
Iron	Molybdenum	Fe_3Mo_2	2300	1150	160	430
Lead	Calcium	Pb_3Ca	600	70	7	19
Nickel	Beryllium	NiBe	1830	840	170	525
Nickel-copper	Aluminum	....	1700	1200	150	300
Nickel-iron	Titanium	Ni_2Ti	1750	1200	140	360
Silver	Copper	Cu	1450	600	45	110

The speed of cooling necessary to preserve a supersaturated solution also varies considerably. Aluminum- and copper-base alloys may require drastic quenching, but for many of the nickel-rich alloys air cooling even in sections up to 1 1/2 in. may suffice.

The reheat for precipitation is critical, both as to temperature and time. The operation frequently is a lengthy one, and overdoing it, such as to develop too coarse a precipitate, can be rectified only by repeating the whole cycle of heat treatment. If the precipitation reaction proceeds spontaneously at room temperature it is usually referred to as *aging*.

6. ENGINEERING ALLOYS

The alloys of engineering and commercial importance are few compared with the almost limitless number of possible mixtures. The tendency is toward fewer alloys and greater standardization to serve the ordinary requirements of industry. The great cost of development in bringing a meritorious novel alloy to the point of availability in all commonly used shapes, sizes, and quantities precludes its trade introduction unless tonnage uses are in sight. On the other hand, the engineer often is in the dilemma of urgently requiring alloys with highly specialized properties in quantities too limited to attract the attention of established sources of supply. The larger producers of metals frequently maintain development departments which have available many unpublished data and can assist in such problems.

STANDARDIZATION. For many alloys and simple metals standard compositions have been prescribed and specifications for their control have been prepared, based on the common experience of producers, users, and engineers. The principal standardizing agencies in the United States for metals are the American Society for Testing Materials, in Philadelphia, the Society of Automotive Engineers, in New York, and the Bureau of Standards, in Washington. In addition, many large industrial organizations issue their own purchase specifications, available on request.

A comprehensive and useful guide to the standard specifications of many industrial, government, and engineering society organizations is the *Cross Index of Chemically Equivalent Specifications and Identification Code*, published by General Motors Corp., Detroit (1945). See also *Standards and Specifications for Metals and Metal Products*, Miscellaneous Publication 120, U. S. National Bureau of Standards, Washington.

TRADE NAMES. In addition to numerically designated standard alloys, there are many proprietary alloys generally bearing names that do not suggest their composition, but similar to standard alloys in properties. There are also many obsolete, named alloys which have been described and have become established in handbooks but which no longer have distinctive properties. There are special lists for the identification of such materials: *List of Alloys*, by W. Campbell, ASTM (1930). *Engineering Alloys*, by N. E. Woldman and R. J. Metzler, ASM (1945); sections in *Metals Handbook*, ASM (1948).

THE APPLICATION OF DATA ON STRENGTH OF METALLIC MATERIALS

By H. W. Gillett

The designer selects materials, chiefly metals if he is a mechanical engineer, to provide the properties essential to the object being designed and decides the geometrical shape and size which, in the material chosen, will allow the object to function under the conditions of service.

Correctness of combination of material and of its shape and size is established by the experience of service. When the previously used material becomes unavailable or too expensive, a substitute is sought; or a new material of improved properties opens the way to design of a better or cheaper object. If the experience of service is lacking, prediction of the behavior of the substitute or the new material must be made on some other basis. The object of a handbook is to present concise and correct information on properties and behavior to allow proper proportioning and shaping of old, substitute, and new materials.

TEST SPECIMENS. The properties of materials are determined by certain conventional tests upon "specimens," often chosen for ease in testing and reproducibility of results. These tests may or may not, and often do not, reproduce the conditions of service. The specimens may or may not, and often do not, exactly represent the quality of the material in, or the size or shape of, the actual object. Hence there are elements of uncertainty in the service behavior which can be fully resolved only by service experience or a carefully planned and controlled simulated service test.

To minimize the uncertainty, there must be added to the quantitative numerical data on conventional properties a qualitative understanding of the unmeasured properties essential in fabrication and in use, and of the peculiarities of the material.

The numerical data cited for a given material, prepared in a particular way, are usually for flawless material, and as a rule are obtained under test conditions which avoid stress concentration. The data are usually obtained by stressing "with the grain" and very often on specimens much smaller than the object to be made. The influences of stress concentration, directional differences, and size effects are not reflected in the conventional data on mechanical properties.

EFFECTS OF PROCESSING. The same material, chemically prepared and fabricated in different ways, may vary not only in the conventional properties on flawless material but the preparation may affect the prevalence of flaws. The recorded data for the prototype material may not be representative of the actual material, whereupon testing of samples of the actual material, either by the manufacturer in the exercise of quality control or by the user prior to acceptance, becomes necessary. In either case, great care needs to be exercised in sampling so that the samples tested truly represent the material for use; a

1-in. diameter or larger, its center may have very mediocre properties. The properties of different steels, each quenched in such section that each hardens fully, when tempered back to the same hardness are practically indistinguishable. Tables and property charts, showing properties versus tempering temperature, really show only the response to tempering, a matter with which the heat treater is concerned but the designer is not, since he calls for a steel tempered to the particular strength he needs, not for one tempered at a given temperature for a given time.

DIRECTIONAL EFFECTS. In rolled or forged material there are directional effects resulting from stretching or compressing the material more in one direction than in another. In making gears from forged blanks, great care is exerted to work the blank so that the "grain never cuts across the teeth." Directional properties are more pronounced in alloys with more than one metallographic constituent and, especially, when nonmetallic inclusions are present. Yet, even in pure metal, directional properties may result from orientation of the constituent crystals in definite relation to the direction of rolling. For example, cold-rolled pure copper, pressed into cups, will show four "ears," representing differences in deformability of the copper crystal in different directions.

Directional effects are particularly prone to appear in steel because all steel contains certain nonmetallic inclusions, notably manganese sulfide, which is plastic at steel-working temperatures. The manganese sulfide particles, globular in the ingot, are rolled out into flattened plates or leaves, or into stringers extending in the direction of rolling. Brittle inclusions are strung out into "stepping stones." Cross rolling of plate makes the inclusions shorter and wider and with less effect on properties, but the laminations still exist in the through-plate direction.

Formability is reduced when the inclusions lie across the direction of bending. Static strength is not vastly reduced, but cracking starts at a smaller angle of bend. The inclusions decrease the transverse fatigue strength and the notched-bar impact values of transverse specimens.

How striking the directional differences may be is brought out in the tables on p. 2-05, Section 2. The cited values in handbooks and manufacturers' tables are almost invariably for specimens taken longitudinally; unless the designer is entirely certain that stresses in service will only be applied longitudinally, such specimens give a falsely rosy picture. Directional differences, usually of less vital nature, also result from micro or macro segregation in the ingot, causing a banded structure upon rolling, in which carbide-rich, strong, and possibly brittle bands are sandwiched between weak, carbide-poor bands. This structure often looks worse than it really is, but in extreme cases it may lead to inferior directional properties.

Castings which receive no mechanical work are almost free from directional properties. Specimens from the castings may not appear as good as specimens of comparable wrought material taken in the direction of working, but when transverse specimens of the wrought material are considered the casting might often prove more reliable.

The highest degree of directional difference is naturally met in screw stock that is exceptionally high in sulfur and hence in manganese sulfide. The foreign particles are intentionally introduced to favor machinability, this advantage outweighing, for many lightly loaded uses, the depreciation in transverse properties. For severe service, such steels are not considered safe.

Machinability is enhanced without marked depreciation of transverse properties by the use of 0.10 to 0.20% lead (Ref. 10) instead of large amounts of manganese sulfide. The lead particles appear to be in an extremely fine state of subdivision, not readily detected by the microscope even at high magnification.

SURFACE CONDITIONS. A further drawback to published values is that they are universally given from tests on specimens that have had the surface rather deeply machined off. Mill scale and surface roughness, which, obviously, will act as stress raisers, can be seen with the naked eye. When such material is to be used with the mill surface, test data should clearly be obtained without removing the surface. A more insidious surface defect is the presence of a decarburized "bark," which is not visible to the naked eye but requires metallographic examination for detection. The bark may be thin and not made clearly evident by hardness determinations.

These surface defects may or may not be serious in static loading, but they are highly serious under repeated stress. Fatigue strength decreases as carbon content decreases, and a fatigue crack, started at the weak surface, even though that surface is almost infinitesimally thin, can readily propagate through the interior. Moreover, when shot peening is applied in order to strengthen a surface against fatigue, the decarburized skin is not strengthened to the proper degree.

NEED FOR SIMULATED SERVICE TESTING. For all these reasons, ordinary tabular handbook or manufacturers' data should be examined with a critical eye, to learn whether they represent the size, direction, and surface condition characteristic of the actual service of the part to be made from that alloy or lot. Since there is seldom sufficient information to be had from published data, much less reliance is placed on supposedly representative data from conventional mechanical tests and much more on simulated service testing of the actual, full-sized part, stressed as it will be stressed in service.

THE DUCTILITY PROBLEM. In ordinary static tensile loading, ability to flow a trifle without cracking, thus to redistribute and even out a localized applied stress, as around a rivet hole, has utility; but the usable deformation is very low, generally taken to be of the order of 1%. Ability for such small deformation separates materials into (1) those which are glass brittle and will stand no misalignment whatever; (2) those like cast iron, ordinarily classed as brittle, but having some degree of toughness; and (3) ordinary metals and alloys with tensile ductility ranging from a very small percentage up to taffy-like behavior.

Glass itself is a useful material of construction, in its proper place. The cast-iron class also has its obvious uses. An outstanding example of a material, in this class as to brittleness, that is serving admirably where external toughness used to be called for is the Ford cast crankshaft alloy. With only a trace of tensile ductility or notched-bar impact resistance, these cast crankshafts are used instead of steel forgings in which very high toughness used to be specified. In crankshaft service, rigidity and fatigue resistance are called for; whereas any measurable plastic deformation makes the crankshaft valueless. The ductility of the forging cannot be used. An automobile fender, however, properly calls for material capable of plastic deformation.

In the third class is included cold-drawn bridge wire, classed as one of our most dependable materials of construction, yet having only some 2 to 6% tensile elongation. Big guns with 5% elongation have stood up all right in service.

The numerical value of a figure for elongation means nothing in itself; it has meaning only in relation to the level of ductility expected in normally processed material of that composition. Reduction of area is in the same category. Various useless "merit indices" have been suggested for heat-treated steels, in which great weight is given to the reduction of area determined on longitudinal specimens. Reduction of area is highly sensitive to direction of working: a steel showing 60% in the longitudinal direction will often show 35% on a specimen taken at a 30-degree angle to the direction of working.

High-strength aluminum alloys with 12% elongation and less were tried out with trepidation in place of older, weaker alloys of 18% elongation, but proved quite as dependable. It has been shown (Ref. 11) that an airplane wing would be useless were it to undergo 1 1/2% plastic deformation. The ability for larger plastic deformation in the alloy of the wing is unusable. Nowadays it is recognized that each alloy has a characteristic level of ductility representative of its own goodness, but the goodness is not regulated by the level itself.

Failure to show the expected level, whatever that is, is a sign to the metallurgist of some unexpected happening in the preparation and processing. The happening might be bad in respect to some attribute not measured by the conventional test. This works both ways. If a steel casting supposedly of given composition and heat treatment showed the ductility ordinarily met in wrought stock of that composition and treatment, when tested on a *longitudinal* wrought specimen, it would be suspected that something had gone wrong somewhere, and it would ordinarily turn out that the steel casting had low yield strength.

The need for toughness depends entirely upon the type of service to be met: and when toughness is required, specific proof that it exists, in the actual part, in the actual service is needed. The indirect evidence of conventional tensile and impact tests is insufficient. The significance of the tension test has been fully discussed in Ref. 12.

Data from conventional tests that are recorded in percentage or other values instead of pounds per square inch, such as elongation and reduction of area in the tensile test, do not apply directly in design. They are indirect measures of cold formability in fabrication and show whether the material has the usual characteristics expected upon correct processing.

Less readily evaluated features, such as machinability and weldability, often play a larger part in selection than the more measurable qualities. It is particularly to be noted that notched-bar impact data, reported in foot-pounds energy absorbed by a certain size of specimen with a specified notch, cannot be correctly expressed in foot-pounds per square inch and converted to give data for any other size or notch. Moreover, the figure for energy absorbed in a notched-bar impact test bears no relation whatever to behavior in notched fatigue.

9. ALTERNATE MATERIALS AND PRODUCTION METHODS

Many parts are so lightly loaded that neither static nor fatigue failure is at all likely, nor is wear or corrosion resistance a major factor. Where the piece must have definite contour and dimensions, but few other requirements, a wide variety of materials and methods present themselves for choice, the choice resting on cost of the finished piece. Because this piece or an analogous one was formerly made in a given way from a given material is no reason for clinging to that material and method in the next case, especially where the quantity to be produced is large enough to amortize the equipment required for a different process. Changes in raw-material cost and availability, and technical advances in processing, continually shift the economic picture.

Often the real criterion is how close to final dimensions the piece can be made so as to require the least and the easiest and fastest machining. A small, lightly loaded gear, for example, could be stamped from brass sheet, requiring a die and some finishing, or be made of an aluminum alloy extrusion, again requiring a die, the gear being sliced off by sawing the extrusion. It could be sand cast in gray iron, malleable iron, or secondary aluminum alloy, allowing appreciable finish when machined; it could be die cast very closely to dimensions in a zinc-base die casting, alternately in aluminum; or it could be made from iron powder by die pressing, sintering, and repressing in a coining die.

Other objects might be made on automatic machines from steel, brass, or aluminum free-machining stocks. Brass casting in plaster molds might also be considered. Offhand, the aluminum extrusion and the zinc-base die casting might be given primary consideration for long runs. A meter case with bosses and attachment holes could be made as a sand casting of several alternate materials, as a die casting or pressed from sheet steel with the bosses, which might be made by a screw machine, attached by copper brazing, or by a variety of welding processes. Silver brazing also finds increasing use.

In particular cases, use of seamless or welded tubing or centrifugally cast tubes would offer a choice, affected by the tube dimensions. Centrifugal casting is a logical choice for tubular-type objects, but it is also applied to many patterns normally cast by static pouring. Smaller gates and risers, hence less scrap to remelt, are required than in static casting. Permanent and semipermanent molds are used to secure closer dimensions than in sand casting.

Precision casting, by the lost wax process, long used in dentistry, is applicable to some alloys for high-temperature use that could not otherwise be made to the required dimensional tolerances. (See Section 19, Articles 22 to 24.)

Where a wear-resistant surface, or one with greater strength than the body of the metal, is wanted, carburized, cyanided, or nitrided cases may be applied. Since it is the surface that counts, a very thin case, backed up by a rather strong core, is increasingly used in place of heavy carburized cases on very soft cores. This change is made in order to save processing time and because once a crack is formed in a brittle case it propagates readily through a core, making the core act brittle despite great toughness of the core with the case removed.

Electroplated coatings, for example, chromium, metal-spray coatings, and puddled-on special wear-resistant surface coatings, are used for special cases where wear resistance is needed.

Of great importance in this connection are the induction and flame-hardening processes, carried out with great rapidity, fitting into production lines and providing a hard, strong surface as well as introducing useful compressive stress at the surface. Shot peening, similarly, both hardens the surface and introduces compressive stress. Cheap carbon and low-alloy steels are suitable for these surface treatments. Many alternates are thus available for uses for which heavily carburized, high-alloy steels used to be specified.

Appreciation of the limitations of conventional test data on metals, of the vulnerability of metals to notches and unsoundness which can be avoided or mitigated by thoughtful design, and of the many possibilities in alternate steels and alternate methods of fabrication and processing will save the designer from many pitfalls.

HARDNESS, DENSITY, AND COMPRESSIBILITY

10. HARDNESS TESTING OF MATERIALS

Hardness of a substance may be defined as its resistance to penetration by another substance. Several methods of determining hardness, in commercial use, are described in the following paragraphs.

BRINELL HARDNESS NUMBER (abbreviated to BHN, or simply Brinell) is calculated from the diameter of impression left after a hardened steel ball, 10 mm in diameter, is forced with a pressure of 3000 kg (500 kg for soft metals) into a flat surface on the sample to be tested. The procedure provides for a definite time of load application. The hardness number is defined as the load divided by the *spherical* area of the indentation, using the equation

$$\text{BHN} = \frac{P}{(\pi D/2)(D - \sqrt{D^2 - d^2})}$$

where P = load (kg); D = diameter of ball (= 10 mm); d = diameter of indentation (mm). Tables of hardness numbers corresponding to different values of d, calculated from the foregoing formula, are available.

VICKERS PYRAMID HARDNESS (VPH) or diamond pyramid hardness (DPH) is determined from a test similar to the Brinell. The penetrator, however, is a small diamond pyramid (136°) with a square base, and the load is much lighter, permitting its use on thinner specimens than is possible with the Brinell test. Depth of the indentation can be as little as 0.002-in. The formula for calculation of hardness is

$$\text{VPH} = \frac{1.8544 \times (\text{Load})}{(\text{Diagonal of indentation})^2}$$

By varying the load, hardness determinations may be made on a wide range of alloys, from the hardest to the softest, without the necessity of shifting from one scale to another.

KNOOP HARDNESS NUMBER (KHN) is determined from the use of a diamond indenter in the form of a pyramid, with a rectangular base, and having 172° 30′ longitudinal angle and 130° 0′ transverse angle. The impression is shallow and about three times as long as that produced by the Vickers pyramid at the same load. The long diagonal does not change dimension when the load is removed, but the short diagonal shortens because of the elastic recovery of the material. The hardness is obtained by dividing the load in kilograms by the *unrecovered* projected area of indentation in square millimeters. The formula is

$$\text{KHN} = \frac{L}{l^2 Cp}$$

where L = load (kg); l = measured length of long diagonal of indentation (mm); and Cp = constant relating l to projected area = 7.028×10^{-2} for the indenter described in the foregoing. The Knoop indenter is generally used in the Tukon tester, which applies a known weight through a balance beam, the load being varied according to the hardness of the material to be tested. With loads of 200 grams or over, the Knoop hardness figures do not vary much with load and coincide with those of the Vickers for the usual heat-treated steels. At low loads the values depend on load and should be stated in reporting test results.

ROCKWELL HARDNESS is determined by a penetration test similar to the foregoing methods. However, instead of the operator's having to measure the breadth of the im-

Note. The values in this table shown in bold faced type correspond to the values shown in the corresponding joint SAE—ASM—ASTM Committee on Hardness Conversions as printed in ASTM E48-43T, Table 1. Values in ( ) are beyond normal range; given for information only.

pression, the depth of penetration is measured by the testing instrument and indicated as hardness number on a dial indicator. A variety of penetrators and standard loads can be used, giving a series of different scales identified by letters. In reporting tests the scale must always be stated. The regular penetrator is a diamond cone (120° with a slightly rounded cone), and the regular load is 150 kg, giving the Rockwell C scale, sometimes abbreviated to Rc, which is used for the harder metals. For the less hard metals the Rockwell B scale is used, employing a $^1/_{16}$-in. steel ball penetrator and a 100-kg load. The Rockwell method is much faster than the other penetration methods, and produces an indentation on the order of 0.005-in. It is, therefore, suitable for testing thin specimens. For very thin hard surfaces, such as those on nitrided steel, the Rockwell superficial-hardness tester has been devised, the depth of penetration with which is only about 0.002-in.

THE SHORE SCLEROSCOPE employs a diamond-tipped hammer which is dropped from a definite height upon the surface to be tested. The hardness is measured by the height of rebound, the scale being graduated in arbitrary units such that quenched plain high-carbon steels indicate about 100. Inasmuch as the rebound is affected more by the elastic limit of the specimen than by its tensile strength, the Scleroscope does not measure exactly the same type of hardness as the indentation methods.

Because depth of penetration is very small, the instrument can be used on case-hardened surfaces. Being portable it is especially useful for testing on parts too large to be inserted in one of the other types of instruments. It is also popular when a rapid check on production is needed. For general testing work, however, the Scleroscope is not widely used.

HARDNESS CONVERSION TABLES. It is not possible to translate from one arbitrary hardness scale to another with any degree of precision. However, one scale can be calibrated in terms of another for a particular material or type of material. Conversion tables are given in ASTM E48-43T, *Tentative Hardness Conversion Tables for Steel*, and in ASTM E33-42, *Standard Hardness Conversion Table for Cartridge Brass.*

Table 1 provides a general comparison between hardness scales, but it may be in considerable error for some materials, particularly those of high hardness.

MOHS' SCALE is a scratch hardness scale, consisting of a series of minerals each of which can be scratched by the one next above it in the scale. The differences are not uniform, and the intervals between successive numbers increase rapidly as the hardness number increases. The step from 9 to 10 probably is as great as from 1 to 9. This is the Mohs' scale:

Talc	1	Orthoclase	6
Gypsum	2	Quartz	7
Calc spar	3	Topaz	8
Fluor spar	4	Sapphire	9
Apatite	5	Diamond	10

Table 2 gives the relative hardness of various materials according to the Mohs' scale.

Table 2. Hardness of Various Materials by Mohs' Scale

(Data reprinted by permission from the Smithsonian Tables)

Material	Hardness	Material	Hardness	Material	Hardness	Material	Hardness
Agate	7.0	Bismuth	2.5	Gypsum	1.6–2.0	Plat-iridium	6.5
Alabaster	1.7	Boric acid	3.0	Hematite	6.0	Pyrite	6.3
Alum	2.0–2.5	Brass	3.0-4.0	Hornblende	5.5	Quartz	7.0
Aluminum	2.0	Calamine	5.0	Iridium	6.0	Rock-salt	2.0
Amber	2.0–2.5	Calcite	3.0	Iridosmium	7.0	Ross metal	2.5–3.0
Andalusite	7.5	Copper	2.5–3.0	Iron	4.0–5.0	Silver chloride	1.3
Anthracite	2.2	Corundum	9.0	Kaolin	1.0	Sulfur	1.5–2.5
Antimony	3.3	Diamond	10.0	Loess (0° C)	0.3	Stibnite	2.0
Apatite	5.0	Dolomite	3.5–4.0	Magnetite	6.0	Serpentine	3.0–4.0
Aragonite	3.5	Feldspar	6.0	Marble	3.0–4.0	Silver	2.5–3.0

Asphalt	1.0–2.0	Galena	2.5	Opal	4.0–6.0	Tin	1.5
Augite	6.0	Garnet	7.0	Orthoclase	6.0	Topaz	8.0
Barite	3.3	Glass	4.5–6.5	Palladium	4.8	Tourmaline	7.3
Beryl	7.8	Gold	2.5–3.0	Phosphor bronze	4.0	Wax (0° C)	0.2
Bell metal	4.0	Graphite	0.5–1.0	Platinum	4.3	Wood's metal	3.0

11. SPECIFIC GRAVITY

THE SPECIFIC GRAVITY of a solid or liquid substance is the ratio of the mass of a given volume of the substance to the mass of an equal volume of water at some standard temperature. The temperature commonly used in engineering work is 60 F. The temperature used by physicists is 4 C. In the metric system the specific gravity is equal to the density, i.e., to the weight in grams of one cubic centimeter.

The specific gravity of gases is taken as the ratio of the masses of equal volumes of the given gas and of air or hydrogen, usually at 32 F and 29.921 in. of mercury barometric pressure (0 C and 760 mm pressure). It is necessary to state which basis is used, i.e., air = 1 or hydrogen = 1.

Determination of Specific Gravity of Solids. Determine the weight of the body in air; then submerge it in water and determine its weight. If W = weight in air and w = weight when submerged,

$$\text{Specific gravity} = \frac{W}{W - w}$$

If the body is lighter than water, attach to it a weight, w_1, sufficient to sink it. Then

$$\text{Specific gravity} = \frac{W - w_1}{(W - w_1) - w}$$

Given the specific gravity, referred to water at 60 F,

Weight per cu ft = specific gravity × 62.36.
Weight per cu in = specific gravity × 0.036088.
Specific gravity = weight per cu ft × 0.016036.

THE HYDROMETER. The hydrometer is an instrument for determining the density of liquids. It usually is made of glass, and consists of three parts: (1) the upper part, a graduated stem or fine tube of uniform diameter; (2) a bulb, or enlargement of the tube, containing air; and (3) a small bulb at the bottom, containing shot or mercury which causes the instrument to float in a vertical position. The graduations are figures representing either specific gravities or the numbers of an arbitrary scale, as the Baumé, API, Twaddell, or Beck.

The Baumé hydrometer scale is based on the following formulas:

For liquids lighter than water:

$$\text{Specific gravity} = \frac{140}{130 + \text{degrees Baumé}}$$

For liquids heavier than water:

$$\text{Specific gravity} = \frac{145}{145 - \text{degrees Baumé}}$$

The API hydrometer scale, adopted to avoid the confusion incident to two Baumé scales, is recommended by the American Petroleum Institute, the U. S. Bureau of Mines and the U. S. Bureau of Standards for use in the petroleum and oil industries. It is based on the formula

$$\text{Specific gravity } 60/60 \text{ F} = \frac{141.5}{131.5 + \text{degrees API}}$$

Beck Hydrometer Scale. The relation between specific gravity and the Beck hydrometer scale is expressed by the formulas:

For liquids heavier than water:

$$\text{Specific gravity} = \frac{170}{170 - \text{Beck degrees}}$$

For liquids lighter than water:

$$\text{Specific gravity} = \frac{170}{170 + \text{Beck degrees}}$$

Twaddell Hydrometer Scale. The relation between specific gravity and the Twaddell hydrometer scale, used only for liquids heavier than water, is expressed by the formula

$$\text{Specific gravity} = \frac{5 \times \text{Twaddell degrees} + 1000}{1000}$$

Table 3. Specific Gravity and Weight of Solid Substances, Except Metals and Wood

Substance	Specific Gravity	Average Weight, lb per cu ft	Substance	Specific Gravity	Average Weight, lb per cu ft
Asbestos	2.1–2.8	153	Gypsum	2.08–2.4	140
Ashes	....	43	Hornblende	3.2–3.52	210

Table 4. Specific Gravity of Liquids

Water at 39.1 F (sp. gr. = 1.000) weighs 62.43 lb per cu ft

Liquid	Specific Gravity	Liquid	Specific Gravity	Liquid	Specific Gravity
Acid, acetic	1.06	Carbon disulfide	1.293	Oil, neat's-foot	0.913–0.917
carbolic	0.96	Chloroform	1.480	olive	0.918
fluoric	1.50	Ether	0.736	palm	0.905
muriatic	1.20	Gasoline	0.66–0.75	petroleum	0.78–0.88
nitric	1.54	Glycerol	1.260	rape	0.92
phosphoric	1.56	Kerosene	0.78–0.82	resin	0.955
sulfuric, 87%	1.80	Lye, soda, 66%	1.70	sperm	0.88
Alcohol, ethyl, 100%	0.807	Naphtha	0.76	turpentine	0.873
methyl, 100%	0.810	Oil, cottonseed	0.93	whale	0.92
Ammonia, 27.9%	0.891	lard	0.92	Water, 39.1 F	1.00
Benzine	0.899	linseed, boiled	0.942	212 F	0.958
Bromine	3.187	mineral	0.92	sea	1.02–1.03

The Salinometer is a hydrometer used for determining the density of brine solutions. The indications are four times as large as those on the corresponding Baumé scale.

SPECIFIC GRAVITY OF VARIOUS SUBSTANCES. The specific gravity of the useful metals is given in Table 3, p. 1-04. Table 3 on p. 1-29 gives the specific gravity of various solids, except the metals and woods, and Table 4 gives the specific gravity of liquids. For densities of the various woods, see p. 5-73ff.

12. COMPRESSIBILITY

COMPRESSIBILITY OF LIQUIDS. The coefficient of compression of a liquid is $\beta = (1/V_1) \times (V_1 - V_2)/(p_2 - p_1)$, where V_1 and V_2 are the volumes at the same temperature under pressure p_1 and p_2, respectively. In general, as p increases β decreases, rapidly at first and then slowly. The change of β with temperature is large at low pressures but very small at pressures above 1000 to 2000 atm. Values of $\beta \times 10^6$ are given in Table 5, the pressures being measured in megabaryes (1 megabarye = 10^6 dynes per sq cm = 0.987 atm = 14.50 psi). The units of β are megabaryes^{-1}. To convert to square inches per pound, multiply the value of β by 0.06895. *Example:* For glycerol the value of β is 22×10^{-6} megabaryes^{-1}, which is $22 \times 10^{-6} \times 0.06895 = 1.52 \times 10^{-6}$ sq in. per lb.

Table 5. Compressibility of Liquids

(From Smithsonian Tables, by permission)

Liquid	Temp., °C	Pressure, megabaryes	Compressibility, $\beta \times 10^6$
Benzene	17	5	89
	20	200	77
	20	400	67
Carbon tetrachloride	20	200	86
	20	400	73

	40	1,000	33
	40	12,000	9

COMPRESSIBILITY OF SOLIDS. Table 6 gives values of $10^{-6}/\beta$, where β is defined as in the previous paragraph and is in megabaryes^{-1}. Values in the table therefore represent the bulk modulus in megabaryes. To convert to pounds per square inch, multiply the value of $1/\beta$ by 14.5. *Example:* For aluminum $1/\beta = 0.75 \times 10^6$ megabaryes, which is $0.75 \times 10^6 \times 14.5 = 10.9 \times 10^6$ psi.

Table 6. Compressibility of Solids

(From Smithsonian Tables, by permission)

Material	$10^{-6}/\beta$	Material	$10^{-6}/\beta$	Material	$10^{-6}/\beta$
Tungsten	3.7	Silver	1.01	Sodium chloride	.24
Boron	3.0	Aluminum	0.75	Arsenic	.22
Silicon	3.1	Germanium	0.71	Calcium	.175
Platinum	2.6	Zinc	0.57	Potassium chloride	.135
Nickel	2.3	Tin	0.53	Strontium	.120
Molybdenum	2.2	Gallium	0.48	Lithium	.111
Tantalum	1.9	Cadmium	0.46	Phosphorus (red)	.109
Palladium	1.9	Plate glass	0.45	Selenium	.083
Cobalt	1.82	Lead	0.44	Ice	.083
Nichrome	1.79	Thallium	0.43	Sulfur	.078
Iron	1.67	Antimony	0.42	Iodine	.077
Gold	1.67	Quartz	0.37	Sodium	.064
Pyrite	1.4	Magnesium	0.34	Hard rubber	.051
Copper	1.33	Bismuth	0.33	Phosphorus (white)	.049
Manganese	1.19	Graphite	0.33	Potassium	.032
Brass	1.12	Silica glass	0.32	Rubidium	.025
Chromium	1.12	Cerium	0.27	Caesium	.016

COMPRESSIBILITY OF GASES. At moderate temperatures and pressures, the compressibility of a gas is equal to the reciprocal of the pressure, the bulk modulus being equal to the pressure. Where pressures are high or temperatures low, or the gas is not far removed from its boiling point, a more exact relationship is needed. Table 7 gives the relative change of volume of several gases under various pressures and temperatures. For additional data, see *Power* Volume of Kent's *Mechanical Engineers' Handbook*, Sections 1, 4, and 11.

Table 7. Compressibility of Gases

Relative volume at various temperatures and pressures. Volume at 0 C and 1 atm pressure = 1,000,000.

IRON AND STEEL

Iron is a chemical element which, in its pure form, has almost no commercial use. The addition of other elements to iron radically changes its properties, resulting in countless varieties of cast and wrought irons and steels.

Iron is smelted in blast furnaces from *ore* (iron oxide plus impurities) which is reduced by combination of the oxygen with the carbon in *coke*, the impurities being removed in the slag formed by fusion with *limestone* flux. The product of the blast furnace is pig iron containing 3 to 4% carbon, 1 to 3% silicon, 0.3 to 1.5% phosphorus, 0.1 to 1.0% manganese, and under 1% sulfur. Pig iron partly refined in a *cupola* produces the various grades of *cast iron*. By puddling or shotting processes *wrought iron* also is produced from pig iron. Pig iron plus scrap melted in an *open-hearth furnace* with a flux produces *steel*, part of the carbon being burned out and the impurities further removed. Steel is also produced in *Bessemer converters*, and high-grade steel in *electric furnaces*. Alloying elements may be added at appropriate stages in any of these processes.

Cast steel results from pouring into molds of appropriate shape. To produce the infinite varieties of *wrought steel*, the molten metal is cast into *ingots* of suitable size and shape for hot rolling into *blooms* (cross section more than 6 in.), *billets* (less than 6 in.), or *slabs* (wide sections). Blooms and billets are subsequently hot rolled into bars or structural-steel shapes, or formed into forging blanks. Slabs are hot rolled into plate or sheet form. Further hot working produces finished forgings, tubing, rods, etc. Subsequent cold-working operations include cold rolling, wire drawing, stamping and drawing, and cold heading. All the foregoing processes have profound effects on the ultimate properties of the material in the finished part and must be given due consideration in choosing the particular metal or alloy.

1. LIMITATIONS OF MECHANICAL PROPERTY DATA FOR DESIGN

Selection of engineering materials for machine design aims at a final product with the properties demanded by the particular service, at the lowest final cost, which includes both cost of raw material and the cost of fabricating it. The final properties required are frequently not easily measured, nor are they necessarily implied by the usually listed mechanical properties determined by conventional tests and included in usual specifications.

Fitness for fabrication is even less readily measured in truly quantitative terms. *Machinability*, the quality required for fabrication by machining, grinding, honing, and the like, varies with the particular type of machining operation employed and with the criterion imposed, which may be tool life, energy required to cut, or surface finish produced. What may be unmachinable with one type of tool may become readily machinable with another.

Weldability, a property more often required in modern construction than in earlier days, depends on the welding process, on the preheating and postheating that can be applied, and on the atmosphere surrounding the weld as it is being made. What may be unweldable with one technique may be readily weldable with another.

Formability by plastic deformation, hot or cold, likewise depends on the deformation, bend or draw, and on the technique used.

Castability, suitability to be cast into an approximation to finished size without too much stock to be removed by machining, depends not only on the material itself but also on the foundry technique and, importantly, on design, which may facilitate or prevent production of a sound casting.

None of these abilities for fabrication are wholly inherent in the material, independent of the particular process. The economical process among several possible ones depends on the number of pieces to be made. All that can ordinarily be recorded on ability for fabrication consists of qualitative statements on general order of excellence.

Metallurgy. Many problems arise during the processing of materials to the semifinished stage in which they come to the plant of the machine designer. In processing iron and steel, metallurgical problems, of some concern to the designer, are involved. Discussion of metallurgical principles and of iron and steel materials herein will be confined to aspects directly concerning the designer: the specifications for the semifinished material, its amenability for fabrication within the plant that makes machines, and the properties of the finished parts.

Service Conditions. The ultimate requirement of a finished part is that it shall last for the desired life of the whole structure, or, if designed for replacement, that it shall have a predetermined life. The life can be ended by wear or corrosion just as certainly as by actual fracture or by being bent or battered out of shape. The environment—the actual conditions of service—controls wear and corrosion quite as much as do the properties of the material itself. Hence, no quantitative values can be ascribed to the wear and corrosion resistance of materials by themselves, without relation to service.

Design must therefore consider all the conditions of service, not merely those relating to fracture or to unbearable permanent deformation. Only these features—deformation and fracture—are appraised by conventional mechanical tests and quantitatively appraised by those tests expressible in pounds per square inch.

When, and only when, the designer can appraise the conditions of service in pounds per square inch can he apply these test results to design. For resistance to a single static stress, yield strength is applicable to design where failure would come by permanent deformation. For resistance to repeated loading, endurance strength is applicable when failure would come from fatigue fracture, but this requires that the concentrated rather than the average applied stress be known, and that the endurance strength be determined at the same stress concentration. The modulus of elasticity, another pounds-per-square-inch value, is directly applicable for calculation of stiffness.

Other numerical values among those obtained by conventional mechanical testing, such as elongation and reduction of area in the tensile test and energy absorbed by a notched bar in a static bend or an impact test, do not have direct applicability to design; what bearing they have is a matter of implication. That they are matters of implication is illustrated by many familiar examples.

TENSILE DUCTILITY. Ductility in a tensile test is often thought of as insurance against brittle, shattering failure. But much commercial steel, of high tensile ductility, can fail with a brittle fracture, propagated with explosive rapidity, as was demonstrated by wartime failures of welded ships fabricated from steel with a high level of tensile ductility.

Cast iron lacks tensile ductility and may fracture under shock, as happens when cast-iron fittings in a ship are subjected to shock resulting from impact of a projectile elsewhere upon the ship, or to one transmitted to the ship through the water, say from a "near miss" of an explosive charge. But when conditions of service permit no such shock, as in the base of a machine tool, this brittleness is no drawback. Automobile crankshafts used to be specified of high tensile ductility and notched-bar energy absorption on the assumption that a shattering failure would ruin the whole engine. Finally, it was realized that a bent crankshaft was equally ruinous, and that stiffness was a prime necessity. The Ford cast crankshaft, designed for stiffness, and made from a metal with almost zero tensile ductility and notched-bar energy absorption, has been proved adequate by many millions in actual operation.

Local Ductility. In a riveted bridge, various members fail to match exactly, and the initial stress distribution is not the average called for by design but is concentrated at local spots. When this local stress concentration exceeds the yield strength, the surrounding metal stretches locally until the stress is distributed and the other members take up their share. That much ductility is essential, but the necessary amount of permanent deformation is very small. It is local ductility that is needed rather than the general extension measured in the tensile test. Similarly, ability of a material to give locally at the base of a notch and thus relieve stress concentration in fatigue, rather than to extend the notch into a crack, is an asset. But this "crackless plasticity" is not quantitatively measured by the ductility of the tensile test.

Ability to be cold formed without cracking, as in the deep drawing of a complicated automobile fender, does not go hand in hand with conventional tensile ductility, for tensile ductility alone will not unfailingly sort out materials of good and poor behavior. The applied stresses are not purely tensile. A satisfactory test must more closely duplicate the conditions of actual forming.

Ductility, Toughness, and Notch Sensitivity. With very few exceptions, ferrous-base materials, so alloyed, so cold worked, or so heat treated as to be strengthened, have their ductility, notched-bar toughness, and resistance to notch sensitivity in fatigue decreased. But none of these three quantitatively measures either of the other two. Though all three go in the same direction, no two go at the same rate. By experience and analogy it is found that, in material of the same composition, processed in the same manner, to a given yield strength, a certain ductility connotes a certain notch toughness and a certain notch sensitivity in fatigue, but any "conversion factors" so obtained do not hold with exactness for material of another composition or processing. As to notch toughness, supposedly identical heats may act individually, displaying widely different behaviors.

Excessive Ductility. Ductility values may reveal metallurgical differences and thus be a clue to differences in processing, or to internal unsoundness which may not measurably affect yield strength. Thus they are useful indicators to the metallurgist striving to obtain complete uniformity in a product. Many metallic materials have far more ductility than the designer can allow to be displayed in service, and the excess, in itself, is then of no value in the material. Some other property that happens to go along with, but is not measured by, ductility, may be of value. If so, that other property is the one that should be measured.

Big guns, centrifugally cast, autofrettaged, and heat treated to 90,000 to 95,000 psi yield, have been proof and service tested, with satisfactory performance, when made from steel with 5 to 11% elongation and 36 to 48% reduction of area, although it is feasible to get 17 and 60% respectively with proper choice of steel and processing method (Ref. 1). Insistence on greater elongation as "insurance" for steel in less severe service seems scarcely justified.

Each material has its own level of ductility. Ordinary structural bridge steel has some 30% elongation at around 35,000 psi yield strength; cold-drawn bridge wire has some 2 to 6% elongation at around 180,000 psi yield strength. Each needs some ability for permanent deformation when stressed above the yield, in order to redistribute stress, and each has it. Obviously, the structural steel does not need any more ductility than the wire to accomplish this purpose. That it has 30 instead of 2% does not make it any better in service, but if a 35,000-yield-strength structural steel displayed only 6%, it would be obvious that something had gone wrong in its manufacture and it did not represent normal material.

Qualitative information is obtainable from ductility figures. In cast steel, incorrect deoxidation practice makes the ever-present manganese sulfide, which is brittle at room temperature, collect around grain boundaries in films; correct practice forms them as widely separated globules, practically innocuous. If two grains separated by a brittle film are so oriented at the surface of a piece that the boundary is actually a notch, filled by brittle material, the behavior in fatigue will be inferior. Even in the worst cases, the films are not continuous enough to affect the yield strength appreciably, and ample ductility for static loading still remains, but the tensile ductility drops sufficiently to serve as a warning against the use of poorly deoxidized steel for fatigue service. Microscopic examination would give equal information, and the per cent elongation is no quantitative measure of the reduction in endurance.

Low ductility values, perhaps accompanied by low yield strength, may be met in "flaky steel." These "flakes" are unwelded voids, that is, small cracks, generally accepted as resulting from hydrogen in the steel which was first in solid solution but came out of solution at some microscopic imperfection in the steel crystal, the gaseous hydrogen exerting enough pressure to rupture the steel locally. Flakes may appear in some highly alloyed steels, and an analogous defect, shatter cracks, in rail steel. Less obvious analogs to flakes may occur from hydrogen in ordinary cast steel. In rails and small steel castings, controlled cooling, which gives time for hydrogen to diffuse out without collecting as gas within the steel, helps a good deal. Ridding the stiffer high-alloy steels of the effects of hydrogen is more difficult.

Flakes and shatter cracks are nuclei for fatigue failures. Their presence is more clearly shown by metallographic examination or by examination of a fracture than by lowering of tensile ductility or other conventional tests, but lower-than-normal ductility helps to point out, merely in qualitative fashion, the need for specific examination.

Thus, there is some advantage in knowing what ductility normally accompanies a given yield strength, though the ductility values do not provide quantitative design information. For some applications, steel with subnormal ductility might serve quite as well as normal material.

DIRECTIONAL PROPERTIES. The ductility of wrought steel can, and usually does, vary immensely according to the angle at which the test piece is taken in respect to the direction of working. All steel contains nonmetallic inclusions, notably manganese sulfide. This sulfide is plastic at hot-working temperatures and is flattened out into leaflike plates or stringers which interrupt the continuity of the metal matrix in the direction normal to the direction of working. Metallic constituents themselves may give the matrix a banded structure, resulting from an original coarse structure of the two metallographic constituents of steel of usual composition in large, slowly cooled ingots, and the rolling down of these two sorts of crystals, one harder and one softer, into a "banded" structure. The mechanical effects of this are not so marked as those of nonmetallic inclusions, but any wrought steel, no matter how clean, has directional properties if it has received more hot deformation in one direction than in another. The yield strength is not greatly affected by the direction in which the specimen is taken unless the amount of nonmetallic inclusions is very high. Fatigue strength may be reduced. Data have been cited (Ref. 2) for a certain lot of steel, heat treated to 115,000 psi yield, which gave 78,000 psi endurance limit, 59 ft-lb Izod on longitudinal specimens, but only 58,000 psi and 36 ft-lb on transverse specimens. The endurance tests were on unnotched, polished specimens. Gear makers take great care to forge gear blanks so that the "grain" is not transverse to the applied stress at any point.

Lest the citing of endurance and Izod values together should give an erroneous impression, data may be given (Ref. 3) for a nickel-chromium steel, originally with 38 ft-lb notched-bar impact and an endurance limit of 23,500 psi on a threaded specimen. Long-continued use at high temperature dropped the notched-bar value to 4 ft-lb, but the threaded specimen from this embrittled steel still showed 23,500 psi endurance limit. Static notched-bar and notched endurance values have no relation.

Directional differences are evidenced both by ductility and by notched-bar values. The following data on low-alloy, as-rolled plate steel, are illustrative:

Specimen	Tensile Strength, psi	Yield Strength, psi	Elongation, %	Reduction of Area, %
Longitudinal	65,000–75,000	45,000–50,000	30	65
Transverse	65,000–75,000	45,000–50,000	20	55
Normal to plate	65,000–75,000	45,000–50,000	2–4	5–15

Another example is hot-rolled 0.10% C, 0.75% Mn, 0.20% S free-machining bar stock, with:

Specimen	Tensile Strength, psi	Yield Strength, psi	Elongation, %	Charpy Keyhole Impact, ft-lb	Reduction of Area, %
Longitudinal	67,000	40,000	37	16–19 $^1/_2$	60
Transverse	62,300	36,000	22 $^1/_2$	8– 9 $^1/_2$	24 $^1/_2$

Both tensile and notched-bar data are ordinarily reported only as obtained on longitudinal specimens. The designer is seldom informed that directional differences exist. That so much difference does exist in material that has been much used, with satisfactory results, indicates that, in the applications where it has been found satisfactory, there is little actual reason for calling for extremely high longitudinal ductility and toughness, since it would be rare that service stresses would come solely in the longitudinal direction.

High longitudinal ductility is regularly accompanied by lower transverse ductility. Cross rolling of plate tends to equalize the two but does not affect the ductility in the through-plate direction.

Castings are sometimes considered inferior to rolled or forged material of equal yield strength on the basis of lower ductility than that displayed on longitudinal specimens from the wrought material, whereas the lack of directional properties in the casting would reverse the comparison were transverse ductility of the wrought product considered the criterion.

SIZE EFFECTS. Another fallacy is the assumption that reported values for mechanical properties determined on a light rolled or cast section represent the properties of a heavy section. This is true neither in wrought steel as rolled or normalized nor in cast steel. (It is likely to be even farther from the truth in heat-treated steels, as will be discussed later.) The yield strength and ductility of $^1/_2$-in. plate are appreciably higher than those of 2-in. plate, for example.

The properties of castings vary materially with the size of section—this is particularly true of cast iron and noteworthy in cast steel—the larger the section, the lower the strength. The mechanical properties are usually reported from test bars cast separately rather than from sections cut from an actual casting. Good practice for cast iron uses a test bar of section equal to that of the casting, but tabulated values may not take section into account. The test bar for cast steel is ordinarily 1 in. square in section and cast with a very large riser to insure soundness. The casting itself may be much heavier, with resulting lower yield strength, and it is seldom as adequately fed as the test bar is. The test bar results merely tell something about the quality of the molten steel in the ladle. Design of the casting and its gating govern whether good steel makes a sound or unsound casting. For reliability, it is far more important that a casting be sound than that a separate piece of metal have high mechanical properties.

These matters can be summed up in the statement that true sampling is required and that the properties on which design is based must be determined on specimens from the section called for in design. Tabulated values from conventional tests on small specimens are open to question.

NOTCHED-BAR TESTS. Particularly misleading on account of size effect are conventional notched-bar impact tests such as the Charpy and Izod, which are made in the hope that they will tell something about toughness. As already mentioned, ductility values from a tensile test are no sure indication of toughness, brittle fractures occurring in many commercial structural steels of great tensile ductility.

Restraint to Deformation. When steel starts to fracture, it tries to pull out and neck down by plastic deformation. If not restrained, it does move; the fracture is tough and occurs relatively slowly, the tensile specimen exerting little restraint. Steels very high in carbon, unless specially heat treated, or those with medium carbon and very high phosphorus, do not deform much, and they break with a flat fracture even in the tensile test. Similar "stiffness" appears in some steels at extremely low temperatures, and flat fractures can be produced even in tensile tests of such steels at such temperatures even though they are highly ductile at room temperature. Lowering the temperature naturally makes a metal stronger and less plastic, just as raising the temperature tends to make it weaker and more plastic; thus the tensile and yield strengths rise as temperature drops. Ductility in the tensile test, however, is reduced less than the strength is raised. Thus the metal itself shifts in properties and behavior.

However, this behavior is quite different when the metal that is trying to let itself be displaced by plastic flow has no place to go. If the applied stress is localized, as at the base of a notch, the notch has to open its lips and its edges rise above their original position while the base of the notch is rounding off and distributing the stress. If this motion is restrained by adjacent metal instead of being allowed by a free surface, the motion is restricted and, instead of the base of the notch rounding off, a crack starts which may propagate with explosive rapidity (about a mile a second). The behavior thus is specifically related to the geometrical restraint and is a primary function of the size and shape of the piece. Naturally, it depends considerably on the sharpness of the notch, i.e., the degree of stress concentration, as well as on the possibility of relieving the stress concentration. The ability of the metal to move is affected by its own make-up. Coarse grains appear less able to deform than fine ones. The grain boundaries are less restrained than the body of the grain, and, just as on the macro scale a larger metal mass discourages movement, so on the micro scale the larger mass of metal in a coarse grain also discourages it. Lowering the temperature, as mentioned above, makes the metal less able to move under a given stress since its yield strength is increased.

Thus the behavior in a notched-bar test is governed only partly by the nature of the metal but very greatly by the geometry of the piece being fractured. Notched-bar values therefore represent behavior in a particular piece, of given dimensions and given notch sharpness, and can be expressed in foot-pounds for that piece, but not in foot-pounds per square inch for any other piece. Even the Izod and Charpy values cannot be accurately converted one to the other. Thus, such figures do not define the material by itself and are of no direct value in design. The *only* figure of any value in design is that obtained on a *full-sized* piece, with the *exact* stress concentration of service, tested *at* the temperature of service. The conventional notched-bar Charpy specimen with a breaking section of about 0.2 in. by 0.4 in. is extremely tiny compared to most actual structures and exerts small geometrical restraint.

Temperature and Size Effects. In the steels that display brittle behavior in large sections and at lowered temperature, but ductile behavior in small sections at room temperature, the transition from ductile to brittle behavior can occur with suddenness as soon as a limiting size is overstepped or the piece cooled to a limiting temperature. This transition is quite as clearly marked by the type of fracture as by the energy absorbed. The fracture may be ductile, by tearing, around the edges, but flat, by cleavage, in a spot in the center, when restraint becomes too much for plastic flow to continue. With increasing size of piece or decreasing temperature the flat spot increases in size. The actual brittle fractures met in service, as in the failures of welded ships, start with deformation and thinning down of the plate edges at the initial fracture, but as the fracture progresses away from a free surface it shifts to the cleavage type.

Observation of the outline of the fractured surface of a notched-bar specimen gives a picture of the degree of deformation that has occurred. The figure for energy absorbed may be quite misleading, for it may still be high when the periphery is deformed but the center is cleaving without deformation and the piece is actually on the verge of shifting to a preponderantly brittle fracture.

Under transition conditions very slight differences in internal structure or in sharpness of notch will affect the behavior so that some "duplicate" specimens may show high energy absorbed, others very low. If only two or three duplicates are tested it may happen that only high values are obtained and the imminence of transition is not shown. See Fig. 1.

Obviously, if room temperature and a given size and shape of specimen are used, differences in the behavior of different steels will not be shown up unless one steel happens to have its transition temperature above, and the other below, room temperature. Progressively increasing the size of the specimen, as by use of double or triple widths, is more likely to bracket the transition, but the easiest way to bracket it is by using the ordinary specimen at a decreasing range of temperature. Such a series evaluates different steels, and different heats of the same steel, as to their relative dislike for conditions of restraint. The evaluation should be based not merely on energy absorbed, but equally on type of fracture and outline of the fractured piece.

Design. This evaluation by conventional specimens gives qualitative information to the metallurgist in his study of composition, grain size, and finishing practice. But it gives the designer no basis for safe design. Specifications based on energy absorbed by a tiny specimen give the appearance of safe selection of material without the reality. The alloy-steel lining of a liquefied-gas storage tank at Cleveland met the specification of 20 ft-lb Charpy at −260 F on the conventional specimen (Ref. 4). Nevertheless, the tank exploded with disastrous results. The restraint upon deformation in the full-size lining is obviously much greater than in the tiny test specimen.

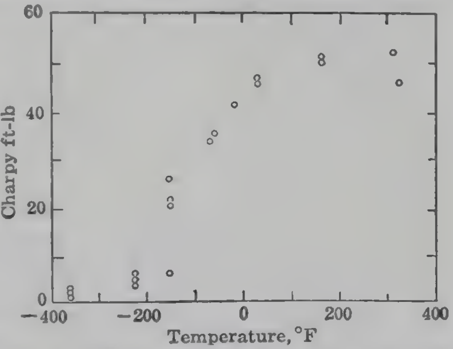

FIG. 1. Charpy impact data for a heat of 1030 steel, normalized. Note the variable results at −150 F.

Designing in layer construction, with thin layers, utilizes the superior geometric toughness of small sections. Pressure vessels, built up by wrapping thin strips upon themselves, have been made to fail only in ductile fashion (Ref. 5) when heavy walled ones might fail in brittle fashion. Large crane hooks built up of a pack of thin plates side by side find safe use where solid ones are likely to fail in brittle fashion.

The low-temperature and size-effect toughness problem is acute only in certain ferrous materials. Commercial nonferrous alloys in general do not display the tough-to-brittle transition, nor do wholly austenitic steels. These materials, if tough at room temperature, remain tough at the lowest temperatures met commercially. If relatively brittle at room temperature, they remain so, but not appreciably more so at low temperature.

Economic requirements do not often permit use of materials not subject to transition of behavior, and steel has to be used. Some unkilled structural steels have the transition at or even above room temperature if the section is large, but this does not prevent their use in small sections or where stress concentration as well as geometrical restraint is absent. Other things being equal, killed structural steels maintain tough behavior to lower temperature than rimmed steels, and, the finer the grain, the lower the temperature.

Fine-grained killed steel, extremely low in carbon and with some of the ferrite-strengthening elements added to make up for deficiency in static strength, shows still lower transition temperature, and heat-treatable steel, quenched to a fully martensitic structure, then tempered, also shows a low transition temperature. (See Fig. 7.) But any of these, under sufficient stress concentration and sufficient restraint upon deformation arising from section and size, can display the transition to brittle behavior at a temperature far above that displayed in the conventional notched-bar test. Therefore, sound design can be based only on full-scale tests with the full stress concentration, restraint, and temperature occurring in service. Nor should it be forgotten that individual heats of steel, supposedly alike, vary in transition behavior according to minor variations in the way they are "killed," so that immunity to brittle behavior shown by one lot on the full-scale test does not guarantee that another lot will have like immunity.

In such connections, the conventional notched-bar impact values stand as a snare and a delusion to the designer. High values may come far from truly indicating utility.

Temper Brittleness. Notched-bar tests reveal a condition, not evidenced by other conventional tests, known as "temper brittleness." Some highly alloyed, quenched steels, tempered at rather high temperatures, show relatively low energy absorbed in the notched-bar test if they have been slowly cooled from the tempering temperature, higher energy absorption if rapidly cooled. Some are brittle if tempered in the range 800–1100 F, even if rapidly cooled. This behavior appears to be due to separation at grain boundaries of some material not completely identified. The effect of this condition on static or fatigue behavior is probably slight, being marked only in single-blow notch tests. This condition is taken seriously by makers of armor, some of whom feel that ballistic and notched-bar behaviors are invariably closely related. Ballistic records, however, show cases of poor ballistic performance with high notch toughness, and vice versa, depending somewhat on the relative sizes of the projectile and the armor. The temper-brittle condition in such steels is alleviated if not entirely removed by the addition of sufficient molybdenum, though it is possible to give an overdose.

Low values from the conventional notched-bar test may lead to avoidance of certain materials because of their indicated "brittleness" when their actual performance belies the term. Regular malleable cast iron has a room-temperature Charpy notched-bar impact value up to 6 or 7 ft-lb, yet it finds use in tank track guides, brackets for 3-in. guns, and a multitude of other applications in which toughness would seem important. Frye (Ref. 6) illustrates some applications to severe service. Makers of malleable iron use a "wedge curl" test rather than a notched-bar test for evaluation of toughness. This test and the room- and low-temperature behavior of various lots of malleable are discussed by Simmons, Rosenthal, and Lorig (Ref. 7).

The metallurgist can get qualitative information from notched-bar values and modes of fracture, but, on the whole, the *designer* can place *no* reliance on conventional notched-bar figures for evaluation of materials. This is a field in which no sample short of the actual piece itself is a true sample. The values are true for the "specimen," fictitious for anything else.

ENDURANCE. Most failures of machine parts are fatigue failures, resulting from repeated stress and starting from some location of stress concentration as a nucleus. Although, under a single static load reaching the yield stress, a metal may deform, distribute the load, and relieve the local stress, stresses below the yield stress do not readily bring this about and the stress concentration remains at a high level. As mentioned earlier, single-blow notched-bar behavior, taking the material to fracture as a single application of stress, is no clue whatever to a metal's behavior in notched fatigue. Tensile ductility values likewise give no direct measure. Notch sensitivity in fatigue is appraisable only by fatigue tests.

Design that is entirely safe for static loading may easily be unsafe for repeated stress because, under repeated stress never reaching the yield stress, fatigue failure results in any but the softest steels, and the fatigue notch sensitivity increases as the static strength increases.

Conventional fatigue tests are made on carefully polished specimens, as free as possible from any notch or other stress raiser. These values are in pounds per square inch and are applicable to design, *if* the actual part is equally well finished, completely free from stress raisers, and always maintained in that condition. Thus, a nicely contoured and polished connecting rod not subject to scratching in use could reasonably be designed on the basis of conventional fatigue data, with due allowance for what stress concentration does exist and for inevitable deviation from perfect axial loading, which will raise the true stress at some location on the surface above the nominal design stress.

Few parts have this ideal initial and continued freedom from stress raisers. An automobile valve spring may remain in good condition and serve well though stressed close to its polished-bar endurance limit. An exposed automobile spring leaf may become roughened by chafing against its neighbors, scratched by grit from the road, and pitted by rusting. Then stress-raising factors soon so depreciate the endurable repeated load that design on the basis of polished-bar values would be unsafe. A polished-bar specimen, unless it faithfully represented any decarburization existing in the actual spring, would not correctly depict even the initial low ability of that spring to carry repeated loads.

Surface Effects. Fatigue fractures start from the surface or, very rarely, from internal stress raisers close to the surface. The surface condition is therefore paramount. Unless a perfect surface is obtained, the notch sensitivity in fatigue comes into play, and this increases with the hardness of the steel. If notch sensitivity were not to be taken into account, fatigue behavior would improve as hardness increases. Since failure starts at the surface, making the surface harder, as by carburizing or nitriding, by induction or flame hardening, or by cold working it, acts to improve endurance of a part; softening it, as by decarburization of the surface, lowers it. Conventional fatigue specimens from which decarburization has been removed do not correctly measure the behavior of parts which do have a decarburized surface. The depth of decarburization beneath the surface makes little difference; it is the extreme surface that is the Achilles' heel, so "only a trace of decarb" may easily be fatal. As for any test, a steel sample for a fatigue test should be a true sample.

Polished-bar fatigue resistance is more closely related to tensile strength and hence to hardness than to any other of the conventional mechanical properties. The endurance ratio (polished endurance limit divided by tensile strength) approximates to a constant 50%, speaking very broadly. Higher or lower ratios, however, are frequent, sometimes being unexplainable, sometimes ascribable to definite causes such as large, sharp-edged inclusions so oriented as to act as stress raisers or to varying degrees of relief of internal stress. The inclusions commercially met are relatively harmless in very soft steels, increasingly harmful as the hardness increases. Since the inclusions at the surface act as stress raisers, this ties in with the notched endurance sensitivity, demonstrated when known notches are created on the surface. If steel is roughened by corrosion, the corrosion pits are stress raisers. Moreover, if corrosion occurs while the steel is being repeatedly stressed, fatigue failure is vastly accelerated, so much so that no endurance limit can be stated for a corrodible steel subjected to corrosion fatigue.

A schematic picture of the relation of polished-bar, notched-bar, and corrosion fatigue behavior in relation to hardness is shown in Fig. 2, which brings out the great penalty paid for design that allows notches or other stress raisers. It shows that, when stress raisers are allowed to be present, little is gained in fatigue resistance by increasing the tensile strength above 125,000 psi, whereas much is gained, up to some 220,000 psi, if there is no stress raiser. The gap between the bands for polished and notched specimens indicates the rising notched endurance sensitivity as hardness increases.

Avoidance, in actual design, of extremely hard steels which, on the basis of yield strength, would appear the better materials of construction is largely based on sad experience with fatigue failures when stress raisers were present. The width of the bands in Fig. 2 indicates that such wide variation in behavior demands more information on fatigue behavior of a given lot of steel than can be secured by analogy with hardness or tensile strength.

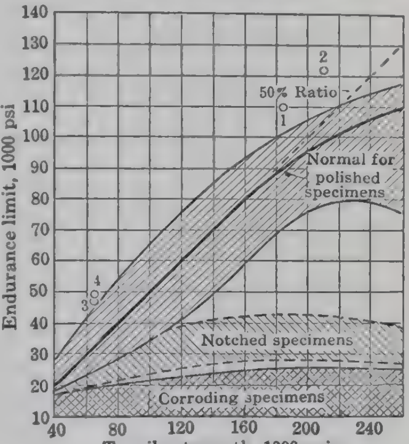

FIG. 2. Relation between tensile strength and endurance limit of steel. Points 1 and 2 are for specimens tempered for extremely long periods of time; points 3 and 4 are for high-phosphorus, mild-alloy steels. (Reproduced by permission from Bullens, *Steel and Its Heat Treatment*, 5th ed., Vol. I, Wiley, 1948)

Design Data. But conventional polished-bar tests, though they evaluate the properties of the steel in a fashion, tell nothing about how it will act in an actual part, with its actual notches or stress concentration. Moreover, there is a size effect in fatigue, though not a very important one. Hence for useful design values the full-sized part, with its actual stress raisers, made from the steel to be studied, must be tested under the actual repeated stress conditions of service. *If* these service stress conditions are known, and design is to be on the basis of indefinite life, with the applied stresses kept below the endurance limit, such tests give design figures.

But the complication generally arises, either that the number and intensity of applied stresses are unknown, or that a limited life will do rather than an infinite life, or both. Design for limited life is based on life at stresses above the endurance limit, where the steel will fail if there are sufficient repetitions of stress. In this range of stresses duplicate tests often show wide scatter, and a great number of tests is required to establish what is the shortest life that may be expected.

Further complication ensues when the repeated stresses are sometimes above and sometimes below the endurance limit. Repeated stresses below the endurance limit strengthen by understressing, and above the limit they damage by overstressing, so that the future behavior in fatigue depends on what number of stresses at what levels have previously been applied. Thus, the practical fatigue problem removes itself from the realm of conventional testing and resolves itself into that of special testing, and special testing of *design* rather than *materials*. That is, notched endurance sensitivity is so predominating that study of the part for locations and levels of stress concentration, by photoelastic study of models, by brittle-lacquer studies, by short gage length electrical strain gages and like methods, followed by redesign to minimize stress concentration, precedes the choice of materials.

If the design cannot be modified to avoid large stress intensification, a relatively soft steel is needed. To the degree that it can be so modified, a harder steel can be applied

No final evaluation of a steel or treatment can be made that is useful for anti-fatigue design without close simulation of the actual design, size, and stress application. Even simulated tests are not easy to plan.

Hence, the designer ordinarily has to fall back on a lively appreciation of the effect of stress raisers in fatigue and a general qualitative understanding of the trends of notched fatigue sensitivity. No tabulated values of notched fatigue resistance can be assembled, and polished-bar values, serving only as a practically unattainable par, would have to be given with plus and minus deviations of the bands in Fig. 2. Some qualitative statements about fatigue resistance of various classes of steel and various microstructures can be made, but such statements cannot be put in "handbook values."

SUMMARY—CONVENTIONAL TESTS OF STEEL. The modulus of elasticity is a sound basis of design for stiffness. Yield strength is a sound, pounds-per-square-inch value for design for static loading. Tensile strength (which can be closely approximated by conversion of hardness values) formerly was used in static design and is applicable if the yield ratio (ratio of yield to tensile strength) of the steels considered is constant. The yield ratio of structural steels is materially increased by alloying and, in heat-treatable steels, by heat treatment. Moreover, design for lack of permanent deformation rather than for complete fracture is customary, and so behavior between the yield and the tensile strengths is not a primary factor.

Ability to yield *slightly* is required in many cases for stress distribution but the required amount of plastic action between the yield strength and the tensile strength is far below that ordinarily present. Ability to yield greatly without fracture is required in some fabrication processes. This ability roughly goes along with, but is not adequately measured by, the ductility values of the tensile test.

Ability to withstand a concentrated applied stress under conditions of severe geometrical restraint, especially when aggravated by low temperature, may be required in service, but tensile ductility is notoriously inadequate in measuring that ability. Conventional notched-bar tests, sometimes alleged to measure this ability, do not measure it, because of an extreme size effect. Special rather than conventional tests are required.

Ability to withstand repeated stress, partly a function of the steel and of its tensile strength, is much more a function of surface condition. Sensitivity to stress raisers is not precisely measured by tensile ductility values. Again, special rather than conventional tests are required for design values.

Directional differences and size effects are shown up by conventional tests only when honest sampling is employed. There remain very few handbook values that can be used, in cookbook recipe fashion, for design without exercise of engineering judgment.

The conventional mechanical tests give, except for yield strength, a generally pseudo-quantitative terminology which really has only qualitative meaning. They indicate conformity to, or deviation from, expected values for steels and treatments, and thus are signposts to the metallurgist of differences, not measured by them, which may in one way or another affect performance, but they do not constitute sound design values.

Within a given class of steels, agreement shown by one steel, or one heat of steel, with the conventional values characteristic of other steels or heats that have behaved well in service may correctly indicate to the designer that the new lot will also behave well, or it may entirely fail to indicate vital differences. Incorrect indications from the conventional values are especially to be feared when different classes of steels, treatments, or structures are compared. To differentiate among classes where conventional values may or may not be useful signposts, the designer must be aware of certain metallurgical facts in making an intelligent exercise of engineering judgment.

2. METALLURGY OF IRON AND STEEL FROM THE DESIGNER'S POINT OF VIEW

Primary factors affecting the structure and properties of iron and steel are *carbon content* and *rate of cooling*.

Carbonless iron is soft and weak. Pure iron is not commercially available in quantity. Both the usual electrolytic product and commercial ingot iron contain appreciable amounts of iron oxide. A nearly all-iron matrix can be produced by binding the carbon of a low-carbon steel to an element that forms an extremely stable carbide. Wrought iron is a very low-carbon material, usually rather high in phosphorus, and invariably containing large amounts of slag, i.e., nonmetallic oxides.

Inclusions. All ferrous products contain small amounts of sulfur. In the presence of iron without manganese, ferrous sulfide exists, tending to embrittle the product. Addition of sufficient manganese causes the formation of a manganese (or manganese-iron) sulfide, with less embrittling tendency, which is plastic at rolling temperatures. All steel contains small amounts of manganese sulfide inclusions, the amount being intentionally increased in free-machining steels. All steel contains at least tiny amounts of other nonmetallic inclusions. All steel contains at least traces of phosphorus. In high-carbon steels, high phosphorus leads to embrittlement; in low-carbon steels, it acts as a strengthening element.

Carbon. Beside these minor amounts of phosphorus, manganese sulfide, and other inclusions, steel contains carbon, as a definite chemical compound, or at least a definite crystal aggregate that amounts to much the same thing as a true chemical compound, called *cementite*. This is iron carbide in which three atoms of iron combine with one of carbon (Fe_3C), or that compound in which part of the iron is replaced by some other carbide-forming element such as manganese, chromium, or molybdenum. Special high-alloy steels may contain other carbides, differing from cementite in chemical composition, crystal structure, and properties. Cementite is hard. The special carbides are even harder.

Steel contains cementite particles distributed through the iron matrix, which matrix is called *ferrite*. The properties of steel are overwhelmingly governed by the amount, size, and distribution of cementite particles within the ferrite matrix. The more the paths through the soft matrix are interrupted by the hard particles, the stronger is the steel. Control of the amount of carbide and its distribution provides primary control over steel properties. The effects of alloys in themselves are minor except as they allow increased control over the distribution of carbide, though they somewhat strengthen the ferrite matrix and, in suitable amount, alter the nature of the carbide.

Slow Cooling. The amount of carbon in steel affects its response to different rates of cooling. In ordinary steels, at forging or rolling temperatures or at temperatures used in heating for quenching, neither of the two separate constituents of cold steel, ferrite and cementite, is present. Ordinary steels, at the high temperature, have only one constituent, called *austenite*, which is iron holding carbon in solid solution. As the austenite cools and passes slowly enough through the "critical temperature" (which depends on the carbon content), the carbon is thrown out of solution, and the iron of the austenite partly transforms to ferrite and partly forms iron carbide. On slow cooling, the iron carbide associates itself with a definite amount of ferrite to form an aggregate called *pearlite*. If the austenite contains 0.83% carbon, all the ferrite is tied up in this aggregate, which is made up of alternate layers of ferrite and cementite. The width of the layers depends on the rate of cooling, and upon this and on the grain-coarsening characteristics of the austenite depends also the size of the individual grains of the pearlite aggregate. Rail steel is nearly all pearlite.

If carbon is less than 0.83%, more ferrite is formed in the transformation than can be held in the pearlite. This excess ferrite is formed first, at a higher temperature than cementite, so that it forms a matrix in which the pearlite patches are embedded. Slow cooling, as in full annealing, produces large pearlite patches or islands in the sea of ferrite; faster cooling, as in air cooling of ordinary sections, gives smaller islands, closer together. Most commercial steels are under 0.83% carbon. If there is more than 0.83% carbon, the excess carbon first separates as cementite, and the matrix is pearlite. Drill rod has such a structure. The presence of alloys usually cuts the 0.83% carbon of pearlite to a slightly lower content, but the relative behavior is the same.

Transformation Temperature. The size and distribution of pearlite patches in the ferrite matrix are governed by the temperature at which the transformation occurs. It takes some time for the carbon atoms in austenite to elbow away the surrounding iron atoms with which they are not going to unite, and then to associate themselves with the ferrite that is going to form pearlite. In the process of cooling, ferrite is being liberated and the pearlite aggregate is collecting into patches. If the austenite is cooled fairly rapidly, these things do not occur at as high a temperature as they would on very slow cooling.

If cooling is very slow, these changes take place at the highest temperature at which they can occur. The resulting structure is coarse, the pearlite patches large, the paths through the ferrite broad and unobstructed; hence the steel, after this "full anneal," is in the softest condition it can attain short of a "spheroidizing anneal" which breaks up the pearlite patches. Faster cooling prevents this aggregation, for the steel is becoming stiffer. It is also possible, by alloying, to make austenite more sluggish, hence to accomplish the same result at a less rapid rate of cooling.

If the transformation can be held back to a lower temperature, the pearlite patches are smaller when deposited, and, once deposited, they stay put. It takes very long heating of the solid ferrite and pearlite to cause the pearlite to break up, free its ferrite and add it to the matrix, and change the cementite layers into balls, though just this can be done by a long "spheroidizing anneal." This is because the solubility of carbon in ferrite and its rate of diffusion in ferrite are very low.

Austenitic Grain Size. On the other hand, the solubility of carbon in austenite is high, and diffusion of carbon in it at elevated temperature is quite rapid. Austenite is solid and exists in crystal grains. If austenite is held at higher temperatures and for longer times, its grains grow. Rejection of excess ferrite begins at the boundaries of the austenite grains, as they start to transform on cooling. Coarse austenite grains therefore favor a more connected ferrite matrix in the ferrite-pearlite structure and lead to a less uniform distribution of pearlite, and it is the uniformity of distribution on which toughness and strength depend. Austenitic grain size is therefore a factor in the properties of the transformed steel when it gets down to room temperature.

Hence, the properties of as-rolled steel, or of steel reheated to the temperature at which austenite exists (the transformation is reversible; the ferrite-pearlite structure becomes austenite on heating), depend not only on the carbon content and on the rate of cooling but also on the grain size (and homogeneity) of the austenite. The rate of cooling depends on the temperature at which the cooling of the austenite is started, on the surrounding medium (still air, air blast, oil, water, brine, etc.) used to abstract the heat from the austenite, and importantly on the size of the piece being cooled. No matter how fast the outside is cooled, heat is not instantaneously abstracted from the center—it can flow only as fast as the low thermal conductivity of steel will allow.

Control of Transformation. Thus the ability to cool austenite fast enough, to make it wait for transformation until it has reached the temperature at which transformation will give the desired structure, is strictly limited by the size of the piece. In a small piece considerable control is possible, but in a very huge piece there is almost none at all upon the center because the center takes its own time to cool even though the skin has been cooled rapidly. The only recourse for control in large sections is to alloy the austenite enough to make it sufficiently sluggish to act as desired under the cooling conditions created. Thus there is a size effect in the heat treatment of steel.

In small enough sections or with a sufficiently sluggish austenite considerable control can be exerted producing, in air cooling, a desirable distribution of ferrite and pearlite. Further control is had by controlling the austenite grain size, as by reheating only slightly into the range of austenite temperatures before cooling, thus giving the austenite small opportunity to grow (but for a long enough time so that it becomes homogeneous), hence getting a fine distribution of pearlite in ferrite on this cooling. (Such reheating and cooling is called normalizing because the structure is considered normal for an air-cooled steel.) Similar control can be applied by introducing tiny amounts of *grain-control elements* which prevent austenite grains from growing until a very high temperature is reached. Fine grain diminishes the tendency toward air hardening, which is to be avoided in normalizing.

Bainite. Indeed, if the section is small enough, and the sluggishness and cooling rate great enough, the transformation can be delayed so far that the regulation pearlite aggregate is not produced. Instead, there results one consisting of patches or needles with less carbon than normal pearlite and with an even finer distribution. This structure is called *bainite*. It ranges from not much stronger than a fine ferrite-pearlite structure to one very much stronger, according to how much the transformation temperature is decreased. However, the structure and the degree of strength produced are highly sensitive to the cooling rate, i.e., to the size effect; hence uniform properties from surface to center are produced only in thin sections whose cooling is arrested at the desired temperature and held there for a more or less extended period.

Martensite. If the transformation temperature can be lowered still further, again by having the section small enough, the rate of cooling high enough (as by quenching instead of air cooling), and the austenite sluggish enough, it is possible to avoid the transformation to ferrite and pearlite or to bainite and to allow austenite to transform to a quite different product, *martensite*. The upper transformations will go on at constant temperature if the steel is held at that temperature. Martensite, however, forms only on a falling temperature.

Martensite, as quenched, is brittle, strong, and very hard, its hardness and brittleness increasing with the carbon content. It consists of ferrite and cementite (or if, as usually considered, of ferrite and carbon, the carbon combines to form cementite on slight heating) with the cementite in a state of subdivision far finer than can be had in the ferrite and pearlite structure or in bainite. Its hardness gives it wear resistance, but its brittleness prevents its use save in certain very special applications. But this brittle material can be toughened, and its static notch sensitivity and notched endurance sensitivity decreased, by heating (*tempering*) through agglomeration of the carbide and thus removing some of the interruption of the paths through the ferrite matrix.

Tempering. The properties of tempered martensite can be varied within wide limits by tempering back to a particular hardness. A high yield strength and high yield ratio are characteristic of tempered martensite. Quenching and tempering provide a range of strengths combined with toughness not otherwise attainable.

Bainite forms both above, and in, the temperature range in which martensite forms. That produced at a very low temperature is nearly as hard as the martensite of the same steel, but the bainite, tempered back to the same hardness as the tempered martensite, has lower yield strength. The ultimate goal in quenching is therefore to produce all martensite without bainite. The goal is not always attainable, nor does it always need to be attained, but the fact remains that a tempered, full-quenched steel, initially all martensite, has higher core strength than a slack-quenched steel whose core is a mixture of tempered martensite and bainite, or some range of bainites, or even so slack quenched as to be ferrite and pearlite. A quenched and tempered spring with a bainite core takes a set at lower load than one that was all martensite, and armor plate whose interior was bainite is not as good armor as one that was all martensite.

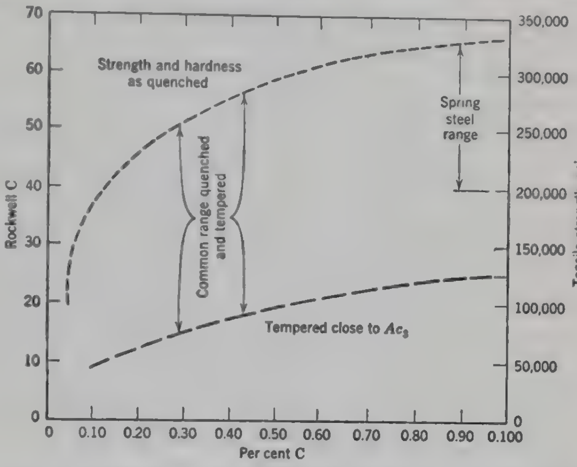

FIG. 3. Range of strength obtainable in steel by varying carbon content and heat treatment. (Reproduced by permission from Bullens, *op. cit.*)

Retained Austenite. By heavy alloying, even the production of martensite may be made incomplete or entirely absent, and the steel may retain some or all austenite at room temperature. This seldom occurs in the steels used in everyday design, though it is intentional in certain steels, notably the 18% chromium 8% nickel type of stainless steel. It occurs in high-speed tool steels and may occur in carburized cases of highly alloyed carburizing steels. Consideration of retained austenite is beyond the scope of the present discussion.

Control of Properties. The range of strength attainable in steel by variation in carbon and heat treatment is shown in Fig. 3. The effect of carbon content in annealed carbon steels, the inverse relation between strength and ductility, and the effect of the ratio of ferrite to pearlite, a result of the carbon content, are shown in Fig. 4.

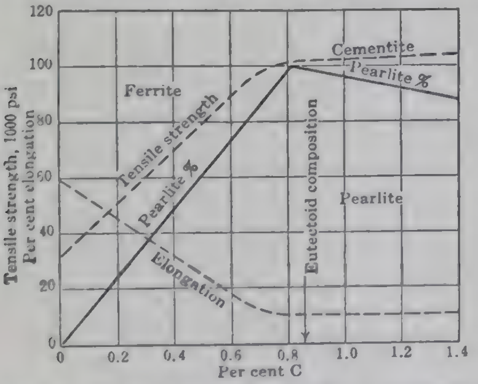

FIG. 4. Ferrite-pearlite-cementite composition (solid lines), compared with tensile strength and elongation of annealed steels. (Reproduced by permission from Bullens, *op. cit.*)

The influence of carbon on the hardness of quenched martensite, before tempering, and in normalized (pearlitic) and drastically annealed (spheroidized) plain carbon steels is shown in Fig. 5*a*. The hardness of martensite is not appreciably influenced by alloy content. The curve is dashed below 0.15% C to indicate that such low-carbon steels, unless accompanied by a huge amount of alloy, do not have the structure of martensite, even when quenched, but bainite or ferrite and pearlite, i.e., a normalized structure.

In ordinary heat treatment of steels with more than 0.60% carbon, the quenched hardness does not increase much above that at 0.60%, because the heating for production of austenite is not high enough to take all the carbide into solution. Therefore, as the lower boundary of the band in Fig. 5*b* shows, the quenched hardness remains at 65 to 67 Rockwell C in spite of the higher carbon; but if all the carbon is taken into solution by use of very high temperature the hardness can be increased, as shown by the upper boundary. This high-temperature treatment is ordinarily avoided because of the danger of excessive grain growth, of oxidation or of decarburization, and other disadvantages.

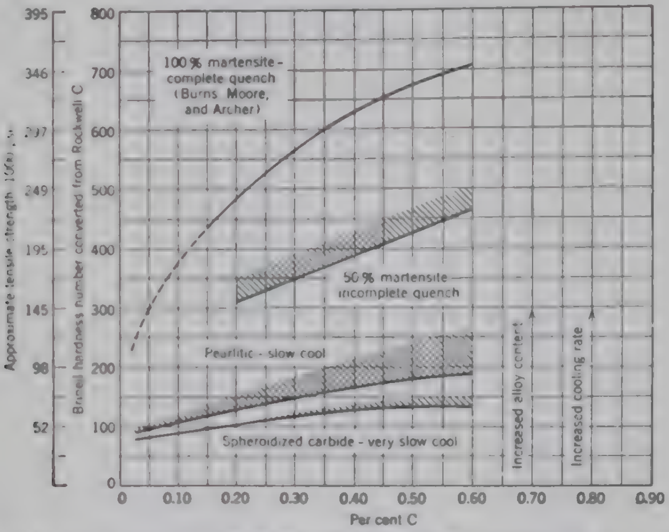

FIG. 5a. Effect of carbon content, method of cooling, and slack quenching on strength and hardness of steel. (Reproduced by permission from Bullens, *op. cit.*)

Carbon Content. Steels for quenching and tempering ordinarily run between 0.25 and 0.50% carbon and still more commonly in the range of 0.30 to 0.40%. Steels for foolproof welding generally run below 0.20% carbon, and below 0.15% if alloyed. Those for deep drawing come closer to 0.10%. Steels to be normalized may run from around 0.10% to, say, 0.40%, depending on section and on alloy content. Cast steels hover closely around 0.25 to 0.30%.

Melting Practice. The carbon level and the degree of need for grain-size control influence the choice of method of melting the steel and the type of deoxidation practice. Steel may be melted in the *open-hearth furnace*, the *converter*, or the *electric furnace*. Any steel save those high in oxidizable alloying elements may be made by any of the processes; those high in such elements are usually made in the electric furnace.

Killed Steel. When fine grain is required it may be produced, especially in the lower-carbon steels, by a normalizing process from not far above the critical temperature of the change to austenite, or by addition of small amounts of grain-size-control elements. These elements are deoxidizers, and steels containing them in amount sufficient for high restraint upon grain growth are *killed*. Other combinations of elements can be used to kill without restraining grain growth. Relatively low-carbon steels may be produced either killed or unkilled. Alloy steels are almost invariably killed. The term arises from the fact that unkilled steel boils and spits in the ladle; killed steels lie "dead."

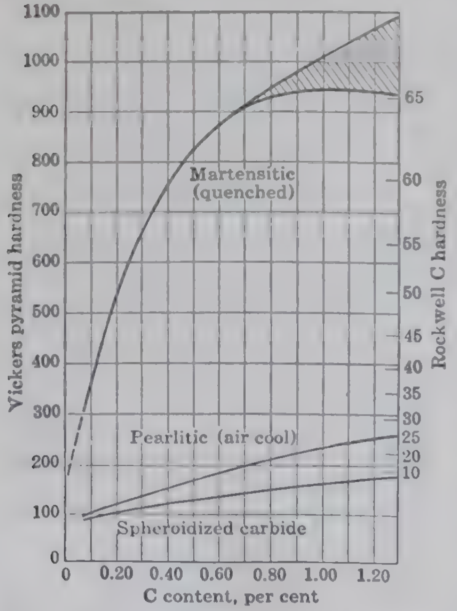

FIG. 5b. Hardness of carbon steels in three structural conditions as a function of carbon content (approximate). Lowest curve shows minimum hardness commercially obtainable. (Reproduced by permission from Bullens, *op. cit.*)

A fully killed steel develops no gas while freezing and, because of the decrease in volume between liquid and solid steel, *pipes* in the ingot, i.e., has a cavity which is at the top and is cut off (*cropped*) from the ingot before rolling if the steel is cast in a *big-end-up* ingot. If the steel is cast in a *big-end-down* ingot, the cavity or cavities are left in, in the hope that they will weld up on rolling.

Unkilled Steel. An unkilled steel in the hot, molten condition contains iron oxide which reacts with the carbon of the steel to form carbon monoxide as the steel cools to the freezing point. The bubbles of gas are trapped in the ingot as it freezes. The conditions are so adjusted by the steelmaker that the ingot does not pipe, the volume shrinkage being balanced by the volume of gas bubbles. The ingot is not cropped, and this absence of discard makes unkilled steel cheaper than killed. Unkilled steel first separates a solid rim of relatively pure ferrite without gas holes. This gives it the name *rimmed* steel. It is also called *open* steel. The core, freezing a bit later, contains more carbon and has the holes. The clean, soft skin gives a nice surface to the final rolled product and to stampings made therefrom. (Unkilled steels are not always rimmed; the holes may come close to the surface.)

Unless the holes fully weld in rolling, the core has some degree of unsoundness which may or may not matter, depending on what fabrication processes and final uses are contemplated. The unsound core is usually avoided in high-strength steels, no matter how that strength is to be achieved. All steel castings, all steels for quenching and tempering, and most steels for normalizing are killed.

Effects of Steel-making Processes. The best quality in high-strength steels is obtained from big-end-up, cropped ingots. The internal pipe in big-end-down ingots results, in the material rolled from the ingot, in good sound material rolled out from those places in the ingot where there happened to be no pipe, but of questionable material from the piped locations. Random tests do not necessarily hit the stock coming from the piped locations.

The cleanliness of the steel—its relative freedom from nonmetallic inclusions—is not related primarily to the method of melting but more to the time and the temperature at which the molten metal is held, though it is considered easier to produce cleaner "aircraft-quality" steel from the electric. Converter steel, of like chemical composition to open-hearth or electric and with like deoxidation practice, has been barred by some specifications, but without reason.

A steel of the same chemical composition can be produced by any of these melting processes or any combination thereof; it may be rimmed or killed; if killed it may be grain size controlled or not, and may be cast in a big-end-up or big-end-down ingot; and it may contain many or few nonmetallic inclusions. Trying to state properties and utility for a given steel composition without mentioning these factors is obviously a too-sweeping effort.

Specifications. All these factors affect the cost of steel, and the mills charge "extras" for applying such variations in practice as increase their production cost of finished steel. If the designer does not need some of these quality features of mill practice to insure satisfactory service of his product, he can save money by not specifying them. If he needs them, it is economy to call for them. The mills are anxious to provide useful material, and their appraisal of fitness for an intended use, when that use is fully described to them, is worth having. Such appraisal may well result in mutually acceptable purchase specifications for chemical composition limits, narrow or wide as the case may justify, grain size, degree of cleanliness, and other factors that make the specification have much more bearing than specifications based on conventional mechanical properties, which notoriously fail to insure the particular deep-drawing properties required for a particular part like an automobile fender.

Reaching a strength level much above that of everyday structural steel requires a normalizing heat treatment at least and, for really high strength, quenching and tempering. Carbon steels have size limitations, under these treatments, which are extended by the introduction of alloying elements. Sales propaganda has tended to obscure some of the vital metallurgical facts affecting the choice of alloy steels. The principles involved are much simpler than they used to be made to appear.

3. METALLURGICAL PRINCIPLES INVOLVED IN STRENGTHENING STEEL

FERRITE STRENGTHENING. A family of "low-alloy high-yield-strength" or, more concisely, "mild-alloy" steels has been built up to meet designers' needs for steel of 50,000 psi yield strength obtained with no heat treatment or the simplest possible heat treatment—mere normalizing—but combining, with this yield strength, high cold formability and foolproof weldability. Raising the carbon content of plain carbon steel to provide this strength depreciates formability and weldability. Low carbon is therefore essential, and, with low carbon, strength has to be supplied in some other way. It is supplied in two ways. Alloying elements make austenite sluggish. If it is thus made sluggish enough to delay its transformation to ferrite and pearlite until a lower temperature is reached than with low and medium straight carbon steels, the pearlite patches are finer and more uniformly distributed. Concurrently, the ferrite matrix is itself made stronger by entrance of alloying elements. This is the second way of strengthening. By what combination of elements these two results are secured is relatively immaterial. Naturally, the elements that are cheap and fairly powerful, or very powerful, even if expensive, have been chosen.

One attribute extraneous to strength has entered into this choice. Long before the days of these steels, it was known that structural steel containing to 0.20% or above of copper (especially if the phosphorus content is somewhat above normal), i.e., so-called copper-bearing steel, acquires a more adherent type of rust when exposed, bare, to the atmosphere, than steels very low in copper and phosphorus and hence (for atmospheric exposure only) subsequently rust more slowly and have a longer life. It *starts* to rust just as fast as the other steels. This ultimate rust resistance was considered a major asset, which it may or may not be, depending on how the steel is actually going to be used and whether it will be kept painted or not.

Both copper and phosphorus are effective in making austenite sluggish and strengthening ferrite. Phosphorus embrittles medium- and high-carbon steels. Roughly, 0.25% as the sum of carbon and phosphorus is the permissible limit. For tough low-temperature behavior, the limit may be lower.

Copper is universally used in this class of steels. Phosphorus appears in a large proportion. Manganese is often made use of. Chromium, nickel, and molybdenum appear in several. Grain-size control plus some strengthening is achieved by vanadium, titanium, or aluminum, alone or in combination.

Table 6, p. 2-43, lists some of the many variations in chemical content displayed by mild alloy steels of closely equivalent mechanical properties, cold formability, and weldability. Broadly speaking, any one can be substituted for any other.

When formability and especially weldability are less important, as in some riveted structures, for example, the carbon content can be raised and a somewhat higher yield strength can be reached, as discussed on p. 2-44.

The properties given are for longitudinal tests on plate $^1/_2$ to $^3/_4$ in. thick. Transverse toughness, of course, will be less. Heavier plate will drop slightly in yield strength and ductility, but yield strength can be raised by increasing alloy content, molybdenum often being used for this purpose.

PRECIPITATION HARDENING. The next upward step for strength in simply treated steels utilizes the precipitation-hardening phenomenon which can be produced in low- and medium-carbon steels containing copper over about 0.60%, most notably with about 1 to 1 $^1/_4$%. Up to around 0.60% the copper is held in solution in the ferrite, strengthening it and conferring the atmospheric corrosion resistance previously mentioned. The excess over about 0.60% is held in apparent solution, even on quite slow cooling, but on reheating to around 1050 F for about an hour this excess is thrown out of solution, in extremely finely divided form, peppered throughout the grains. Just as a fine and uniform distribution of cementite in ferrite raises the strength, so does this distributed material, in spite of the softness of massive copper itself.

This reheating raises the tensile and yield strengths of low- and medium-carbon steels, irrespective of what other alloys are present, by 10,000 to 20,000 psi. Straight carbon, 1% copper steels show such an increase, and, applied to the 50,000 psi yield mild alloy steels containing the proper amount of copper, the reheating brings the yield to around 70,000 psi. Some toughness and ductility are, of course, sacrificed concurrently with the strengthening, but ample remains for most uses. However, in the "solution-treated" state, i.e., before reheating and precipitation, there is high ability for cold forming. The formed article is then reheated for precipitation and strengthening.

This copper-precipitation strengthening is not markedly subject to size effect; the apparent or "forced" solution of the excess copper persists even under remarkably slow rates of cooling, so that even the center of quite large sections retains it until reheated, and uniform strengthening occurs over the whole section. This class of material and type of treatment afford a simple and effective method of getting yield strength well above that of the regular mild-alloy-steel class and bridge a gap between those steels and quenched and tempered steels.

Precipitation hardening occurs in many special alloys especially concocted to utilize the phenomenon, which do not fall within the limits of the present discussion. It occurs as an adventitious, sometimes detrimental, phenomenon in some steels used by the designer. When the precipitation occurs within the grains, useful strengthening tends to result; but when it is confined to grain boundaries, and especially when the precipitated material is itself brittle, it tends toward brittleness. Various compounds are suspected of such precipitation, and it is not always clear just which elements among those that might so act are really responsible. Temper brittleness is suspected as such a phenomenon, and the beneficial effect of molybdenum is suspected to be exerted by causing precipitation in, instead of around, the grains.

Very low-carbon unkilled deep-drawing steels are prone to "aging." When fresh from even slight cold rolling they form without cracking or "stretcher straining," and their stress-strain curves are smooth, without a yield-point jog. A month at room temperature or half an hour in boiling water produces the jog and poorer deep-drawing behavior. Properly killing the steel stabilizes it against such behavior, perhaps by rendering insoluble some minor constituents that otherwise go into solution and then precipitate, or by preventing a sort of annealing of the distorted cold-worked crystals that can go on even at room temperature.

Austenitic steels, such as 18-8 stainless and Hadfield manganese steel, whose austenite contains carbon in solution, can precipitate carbide if held in a certain temperature zone, the brittle carbide being concentrated at the grain boundaries. Some of the properties are thus badly deteriorated.

QUENCHED AND TEMPERED STEELS. In the heat treatment of quenching and tempering necessary for production of higher strength levels, two facts stand out.

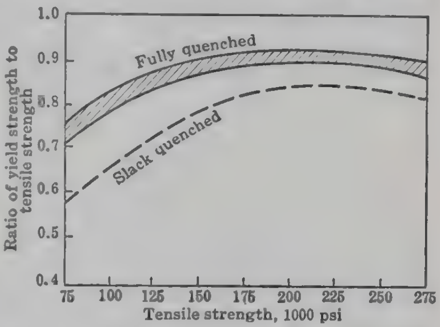

FIG. 6. Loss in yield ratio caused by slack quenching.

First, the yield strength, at given hardness and tensile strength, of any tempered-steel structure that was not initially martensite, before tempering, is inferior to that of a steel initially wholly martensite. That is, the slack-quenched interior of a section that does not harden is inferior when the whole piece has been tempered to the degree desired for the exterior which has hardened to martensite. The degree of inferiority in yield strength and other properties is the greater, the higher the temperature at which the core has transformed to other structures. The effects of slack quenching are brought out in Figs. 5, 6, and 7.

The intended use may not require high core properties. In fatigue the surface is usually the controlling factor. Even under tensile stress where it is intended that the whole section bear its share of the load, loading may easily be so eccentric that the exterior only is of major importance. But some uses do demand equal strength in the interior, and, if the heat-treated piece is ground or machined so that stress concentration, or an actual notch, extends into the weaker material, the piece acts in accordance with the lower strength of that material. Considerable engineering judgment is required in determining what degree of depth hardening is needed in a heat-treated part. Although data are lacking for tabulation of all shades of difference in mechanical properties as one goes from outside to inside of a piece of shallow-hardening, or slack-quenched steel, a hardness survey through the cross section, especially when coupled with metallographic examination of the changing structure through the section, will give qualitative information.

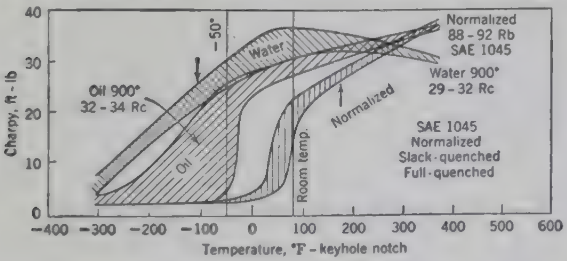

FIG. 7. Notched-bar behavior of 1045 steel heat treated in various ways. In the size used, oil quenching was "slack." (Reproduced by permission from Bullens, *op. cit.*)

As a first approximation, if two steels of the same carbon content are quenched and tempered to the same surface hardness, and their hardness gradients from surface to center are identical, quite similar properties at corresponding points and quite similar service can be expected. This is not necessarily true in every minute detail, but such a situation creates a high probability of close similarity.

The second vital fact about quenched and tempered steels, an even more universally true observation, is that, if two steels of corresponding carbon levels are quenched throughout to all-martensite, and then tempered back to the same hardness, their properties are alike, practically as alike as would be found in duplicate tests of the same steel. Similarity of grain size is also a factor in similarity of properties.

This likeness in other properties at the same hardness level among different steels, without regard to alloy composition, gives a quite different concept from that of earlier days. Then each alloying element or combination thereof was supposed to possess particular advantages or disadvantages relative to the others, depending on which element its proponent was trying to sell. What appeared to be radical differences were displayed in "property charts" of curves for tensile and yield strengths, elongation and reduction of area, perhaps hardness and notched-bar figures, all plotted against tempering temperature for fully quenched, initially martensitic, small specimens. Similarly, the data from which the curves were plotted were given in long tables of properties, with a line for each tempering temperature.

The information in these plots was really temperability, i.e., what temperature, at ordinary tempering times, is required to soften martensite back to a required yield strength.

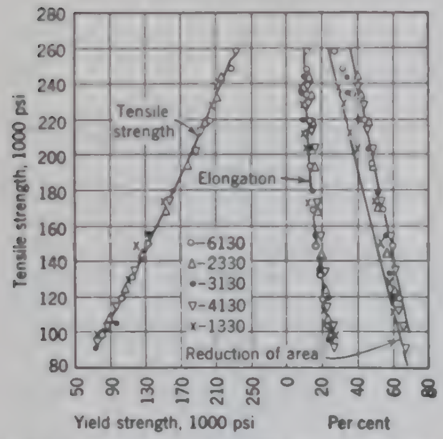

FIG. 8. Properties of various steels of 0.30% carbon content water quenched to martensite and tempered to various strength levels. (Reproduced by permission from Bullens, *op. cit.*)

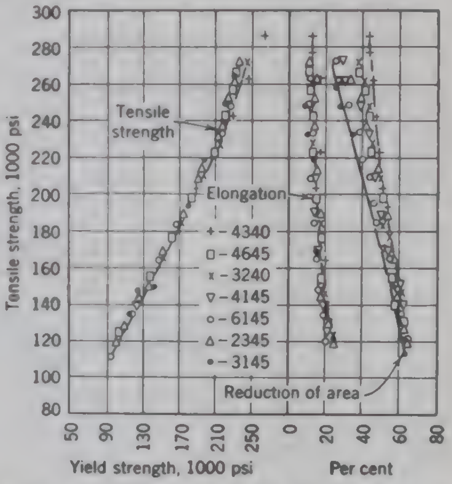

FIG. 9. Properties of various steels of 0.40 to 0.45% carbon content, oil quenched to martensite and tempered to various strength levels. (Reproduced by permission from Bullens, *op. cit.*)

The metallurgist and heat treater are concerned with temperability, but the designer is not; he uses the material in parts that the heat treater has tempered for him.

Quenched and Tempered Steels, Basic Data. When the data are reduced to a tensile strength, yield strength, or hardness basis as has been done by Janitsky and Baeyertz (Ref. 8), Patton (Ref. 9), Herres and Jones (Ref. 10), and many others, plots like Figs. 8 and 9 result, which show that for each strength level up to at least 200,000 psi tensile strength there is a closely defined corresponding yield strength, tensile strength, and elongation and not very much scatter in reduction of area. Even the Izod notched-bar impact values fall pretty close to the same expectation, as Herres and Jones (Fig. 10), also Crafts and Lamont (Ref. 11) show.

For the slack-quenched interior, initially softer than martensite, and further softened by tempering, Fig. 11 shows the relations. At the right of this figure, R_M denotes Rockwell C hardness of martensite, R_Q Rockwell C hardness for that steel as actually quenched. The difference, $R_M - R_Q$, is a measure of the degree of slack quenching, i.e., presence of constituents other than martensite. As the tempering temperature is increased the impact value increases.

Figure 11 was plotted from data on carbon, low-alloy, and high-alloy steels, including the usual SAE and NE steels. Crafts and Lamont say that "the effects of alloying elements are non-specific, so, in general, alloys may be used interchangeably without sacrifice of serviceability." It is hardenability that is conferred by alloys; at the same grain size and with full hardening in quenching, the maximum combination of tensile and impact strength is achieved in the tempered product. The plotted data are for fine-grained steels. Coarse-grained steels have lower toughness than fine-grained steels anyway, but Crafts and Lamont state that, where this is suitably taken into account, the coarse-grained steels show even more reduction in notched-bar values as a result of slack quenching than the fine-grained ones.

Impact strength of tempered steel can be used as a measure of original slack quenching. Thus, applied to the centers of bars of different diameters, it is a measure of hardenability, and Crafts and Lamont give a hardenability table on this basis which corresponds to similar tables based on the more direct Jominy data. Indeed, the end-quenched and tempered Jominy bar can be made into impact specimens with the notch located at the position corresponding to that at the center or at a selected distance from the center of a large bar to give a rough idea of the impact behavior of the heat-treated large bar, were it sampled at the selected location.

At strengths above 200,000 psi tensile, the values for reduction of area and notched-bar values scatter more, because different degrees of stress relief may be obtained at such a level of hardness without affecting hardness and because retained austenite in different amounts will be present in some of the highly alloyed steels, producing such strengths, as well as martensite. Unless the designer has a use to which steel of over 200,000 psi tensile or 180,000 psi yield strength is adapted, these data give no reason for selecting one fully hardened, then tempered, alloy steel over another. It is, indeed, open to question whether the scatter in values at still higher strength levels is not so likely to occur between duplicate heats of the same steel as between different steels. Temper-brittleness effects, which are notably variable from heat to heat, may come into the notched-bar behavior, but if these are eliminated, Herres and Jones extend their smooth curve of expectancy of notched-bar behavior of quenched and tempered steels clear up to 275,000 psi tensile, just as Crafts and Lamont carry their curves to corresponding hardnesses.

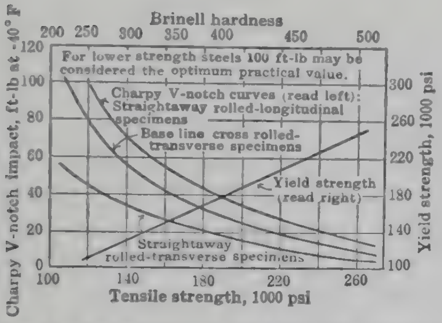

FIG. 10. Relationship of yield strength, Charpy V-notch impact resistance, hardness, and tensile strength of properly heat-treated and fully quenched reasonably clean steel. (Reproduced by permission from A Method for Evaluating Toughness of Steel, by Herres and Jones in *Metal Progress*, Sept. 1946)

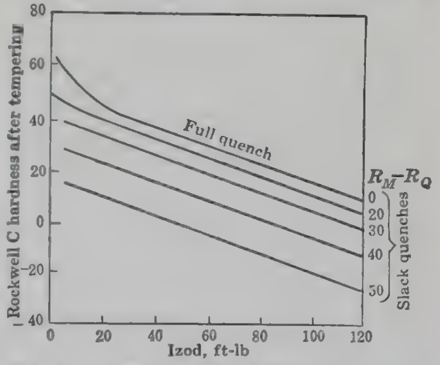

FIG. 11. Loss in notched-bar impact values because of slack quenching. (Adapted from Crafts and Lamont, The Izod Impact Strength of Heat-treated Alloy Steel, *AIMME Tech. Pub.* 2134, *Metals Technol.*, Vol. 14, Feb. 1947)

It is not proved that there is appreciable reliable difference among very hard-quenched and tempered steels of commercial compositions used for constructional purposes, but it is proved that, at least up to 200,000 psi tensile, there is no appreciable difference. Fatigue behavior, to say nothing of machinability, usually sets even a lower limit for the great bulk of design.

This similarity holds only for those steels whose carbide is of the Fe_3C type. When different carbides are produced in high-alloy steels, the behavior can differ. The composition limits at which different carbides are produced are rather well known to all producers of constructional steels, and commercially obtainable steels for constructional purposes seldom fall outside those limits. Special-purpose steels are another story.

Hence, properties of many compositions of steels, instead of being tabulated separately, can be as adequately shown in the master curves of Figs. 8, 9, and 10 for every purpose of the designer. It should be remembered that all these are for longitudinal specimens except as noted in Fig. 10.

Heat Treatment. From the heat treater's point of view, composition has an influence upon proclivity toward or away from cracking on quenching, especially in parts of unbalanced section. If the temperature at which martensite starts to form is too low, quench cracking is likely to occur upon quenching in water or brine, and the more expensive, less effective, oil quench must be used. The martensite-formation temperature is most rapidly depressed by carbon itself, next most rapidly by manganese. Hence, for reasons of processing rather than properties of successfully processed material, the heat treater prefers that both carbon and manganese be limited and that the desired sluggishness of austenite be secured by the addition of other elements less active in depressing the martensite-formation temperature. He also prefers that the temperature of completion of the martensite transformation be above room temperature, else he is confronted with the retention of austenite and the necessity of using cold treatment or repeated temperings to destroy the austenite so that it will not transform during service of the part to brittle, untempered martensite, if the part heats up and then cools off. Within these limits, the heat treater does not care what the composition is. His concern is in the satisfactory production of an all-martensite structure upon quenching.

Were all quenched and tempered sections as thin as watch springs, there would be no demand for alloy constructional steels, only for the special steels. Using alloy constructional steels instead of plain carbon steel in watch springs does not alter their mechanical properties or performance, because the carbon steel quenches to all-martensite. (Securing these properties plus corrosion resistance in watch springs is another matter, requiring alloys that can hardly be called steels.)

Using an alloy steel that will harden throughout, however, would materially improve the properties and performance of a railway car spring, with its large cross section.

Chemical Composition Specification. Alloy steels used to be defined and discussed in terms of chemical composition; to facilitate definition and discussion, the SAE and later the AISI introduced a shorthand numbering system which designates the alloy group and the carbon content and, by establishment of permissible ranges for the variation in carbon and each other element from heat to heat, also conveys a crude idea of the way each so-classified steel will harden on quenching. This depth-hardening behavior was merely implied and not directly expressed. As a matter of fact, within these "permissible" ranges the hardenability could vary widely. In order to insure that the hardenability needed for the section to be quenched would be obtained when a heat on the low-hardenability side was encountered, it was practically necessary to specify a steel of a second, higher-hardenability class than would have served had the hardenability of the first class been uniform instead of variable. This meant that the higher-hardenability heats of the second class might have the martensite-formation temperature so low that quench cracking appeared in such heats under the quenching practice necessary for the low-hardenability heats. Moreover, the higher alloy content of the second class of steels made it more expensive. To solve this dilemma, users began to narrow the chemical composition ranges so as to secure more uniform hardenability, and this made mill control far more difficult, calling for price extras that increase the cost of the steel.

Hardenability Specification. That hardenability and uniform hardenability were prime desiderata in steels for quenching has long been recognized, and it is beginning to be recognized that a more logical system of classification would be on the basis of hardenability: for instance, all steels that harden to martensite at the center when commercially water quenched in $^1/_2$ in. diameter but not in $^3/_4$ in. would be in one classification; those hardening in $^3/_4$ in. but not 1 in. in another, and so on; likewise those that harden on oil quenching in such section ranges. To test a heat for such behavior by quenching and sectioning for examination all sizes involved, say from $^1/_2$ to 2 in. or 1 $^1/_2$ to 4 in., as the case might be, would entail much trouble and expense.

However, a quick and simple test has been devised which gives equivalent information on a single specimen. It has become a conventional test for ability to be processed. It does not directly give design data, but it does evaluate uniformity in hardenability, and uniform hardenability plus proper heat treatment insures that the mechanical properties of the quenched and tempered piece will be so uniform and reproducible that mere hardness testing is ordinarily adequate for appraisal of the properties wanted by the designer, without necessity for expensive tensile testing of the finished product.

Chemical appraisal thus gives way to appraisal by hardenability, although we are still in the transition stage where alloy steels are referred to by AISI numbers, and hence by alloy composition, rather than merely by carbon content and hardenable diameter.

END QUENCH HARDENABILITY TESTING. The conventional test for hardenability consists in heating a specimen 1 in. in diameter by 4 to 6 in. long, to the temperature (and for the time) to be used in actual heating of the steel for quenching, and directing a stream of water upon one end face only, the length and the other end contacting air but no water. The piece thus has all gradations from the fully quenched end through a slack-quenched, down to a merely air-cooled, normalized structure.

Jominy Curves. A small flat is carefully ground along the length of the bar, and the hardness gradient is determined by hardness tests, usually Rockwell C, at spaced intervals. When radically different steels are being compared, metallographic examination is made along the bar length to show how far pure martensite extends and what the gradation through bainite down to ferrite and pearlite is. The data are then plotted as hardness against distance from the quenched end, also in terms of per cent martensite, bainite, and ferrite, plus pearlite at the various distances. From the name of one of its originators, the plot of hardness against distance is usually called a "Jominy curve." A similar plot can also be made after tempering the end-quenched bar to evaluate temperability.

By means of suitable conversion factors, based on experiment, the Jominy distances determined on the end-quenched bar can be converted to those that would be obtained were the specimen end-quenched by oil instead of water. Either set of distances can be converted into the diameter of a bar which, so quenched, will harden at its center to all-martensite or to any chosen percentage of martensite mixed with bainite. This size information is what is wanted. Thus, by the Jominy test the depth of full quenching and of slack quenching of the particular lot tested is experimentally established. A modification of the bar is used when extremely shallow-hardening steels are evaluated, but the principle is the same.

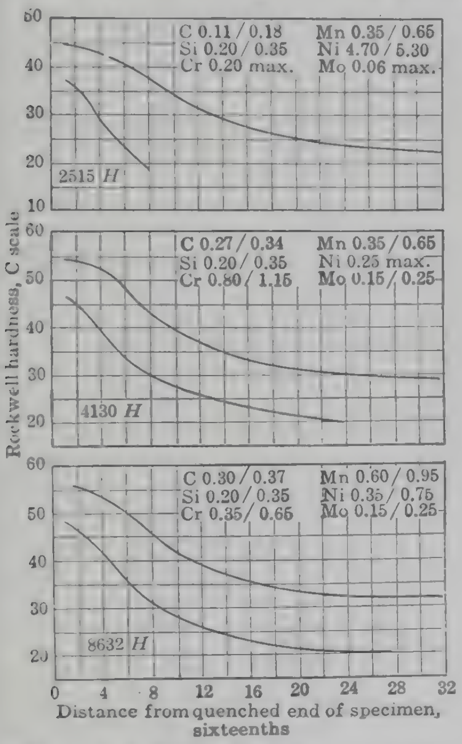

FIG. 12. End-quench test (Jominy) curves and bands. (Reproduced by permission from Bullens, *op. cit.*)

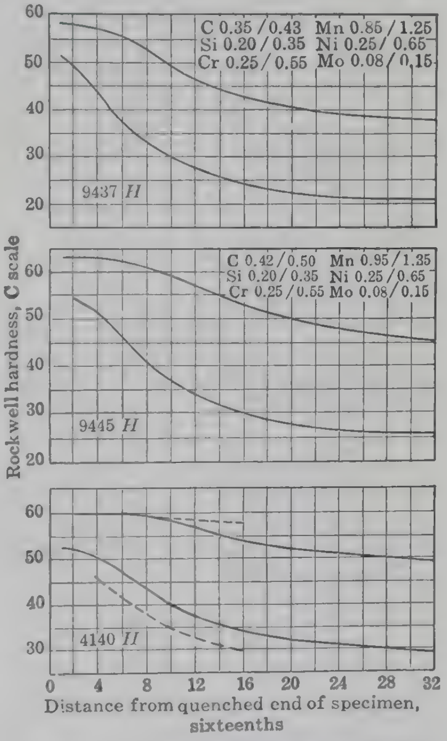

FIG. 13. End-quench test (Jominy) curves and bands. On bottom chart solid line is for 4140H, dotted line for standard chemical composition. (Adapted by permission from Bullens, *op. cit.*)

For any one heat of steel, with the same time and temperature of heating before quenching, there is a characteristic Jominy curve, reasonably reproducible in duplicate tests. Different heats of the same composition, ostensibly processed alike in melting and "finishing," often show differences, and so for one composition the curve is a (narrow) band. For compositions ranging from everything on the high side to everything on the low side in chemistry, within the range permitted by the definitions of steel classes designated by SAE or AISI numbers, the band is extremely wide. Figures 12 and 13 are examples of Jominy curves and bands. As a result of this method of approach, hardenability information can be expressed in extremely comprehensive form, as in Fig. 14.

H Steels. Steels approximately conforming to chemical limits expressed by AISI numbers but falling within more restricted hardenability limits are commercially obtainable as H, i.e., controlled hardenability, steels without a price extra for observing the hardenability limits. Hardenability bands for such steels have been published (Refs. 12,

(Continued on p. 2-24)

13, 14), and the average expectancy for center hardness and per cent martensite, grouped according to carbon levels, is given in Table 1. Chemical composition ranges for the AISI steels and their old SAE equivalents are given in Tables 2 to 5. Some NE steels were used for a time, then abandoned. The compositions of the obsolete ones are on record (Ref. 15).

The degree of conformity with the average hardenability expectations of any particular heat is ascertainable by an actual Jominy test, when more precise information is wanted than is provided by the fact that the heat has been supplied as an H steel, so that its Jominy curve is known to be within the band. Heats unpedigreed as to hardenability can likewise be put into their true category by actual Jominy test.

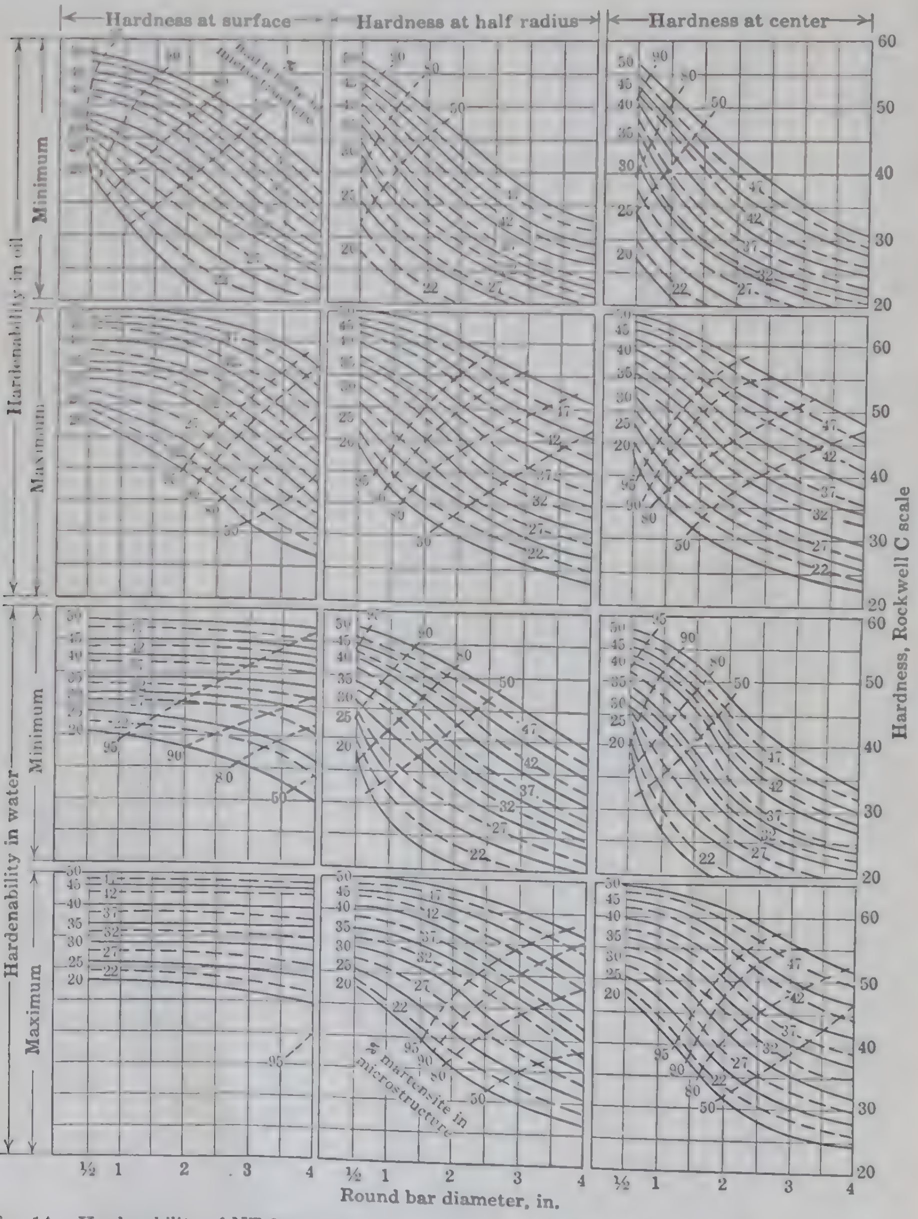

FIG. 14. Hardenability of NE 8600H steels. Mean carbon content is shown on each curve. (Reproduced by permission from a data sheet by A. L. Boegehold in *Metal Progress*, Dec. 1946)

Note on silicon content. When silicon is specified in standard basic open-hearth steels, silicon may be ordered only as 0.10% max, 0.10 to 0.20%, or 0.15 to 0.30%. In the case of many grades of basic open-hearth steel, special practice is necessary in order to comply with a specification including silicon. Acid Bessemer steel is not furnished with specified silicon content.

* Code for prefix letters: B is acid Bessemer carbon steel. C is basic open-hearth carbon steel. D is acid open-hearth carbon steel.

† Phosphorus and sulfur are maximum for basic open-hearth and acid Bessemer steels; sulfurized or phosphorized steels are not subject to check analysis for sulfur or phosphorus.

‡ This steel was dropped from the AISI lists of standard steels dated July 1, 1946.

§ Specifications are for both hot-rolled bars and cold-finished bars.

‖ B 1006 and B 1010 are standard basic open-hearth and acid Bessemer steels for rods and wire.

It might be asked why hardenability, since it is related to chemical composition, is not computed from the chemical analyses. As a rough first approximation, it can be, but in the absence of a very complete chemical analysis and full knowledge of grain size and of all details of finishing the heat, including the use of hardenability-conferring agents, some of which are effective when present in mere traces, the method is likely to be woefully inaccurate.

Despite much effort, and many publications, on hardenability calculations they can be dismissed as inadequate, often highly misleading, and not to be compared in value with the direct information from an actual Jominy test. This situation results from the fact that the effect of a given amount of a given alloy is vastly modified by what amounts of what other alloys are present, so that the straight-line relations necessary for mathematical computation do not hold for many commercial compositions.

Low-alloy Steels. The advent of hardenability testing as an inspection tool and of hardenability limits as a means of purchase specification has resulted in the rise of steels of adequate hardenability for a wide variety of uses that can be made more cheaply than former steels of like hardenability. These arose as a wartime expedient for conservation of scarce alloying elements and maximum utilization of the alloying elements in scrap. At that time they were known as the National Emergency or NE steels (Table 4). Their cheapness, utility, and wide commercial acceptance have since put them into the category of AISI numbered steels, and they are no longer thought of as temporary expedients. The 8600 series has become the most-used series among the alloy steels.

The use of these steels has emphasized the importance, in respect both to cost and to behavior, of exactly matching the hardenability of the steel with the size of the section to be hardened. Deficiency in hardenability sacrifices yield strength in the interior of the slack-quenched steel, and excess hardenability invites quench cracking.

For the designer, this means that a part formerly made from a high-alloy steel, different lots of which had different hardenability, may to advantage be made instead from a lower-alloy steel of controlled hardenability. "What used to be used" is not the modern engineering criterion for selection of steels.

NOTES: (*a*) Eliminated from AISI Standards, as revised July 1, 1946. (*b*) Sulfur range: 0.035 to 0.050%.

* Prefix A means basic open-hearth alloy steel. E means electric furnace steel.

† Lowest standard maximum phosphorus or sulfur content for acid open-hearth or acid electric furnace alloy steel is 0.05% each; silicon is 0.15% min.

* All National Emergency steels are subject to the conditions concerning chemical ranges and phosphorus and sulfur maxima as outlined for standard alloy steels on pages 19 and 20 inclusive in the latest revision of American Iron & Steel Institute's *Steel Product Manual* 10, entitled "Alloy Steels" and to the standard permissible variations from specified ranges as listed on page 27 of that *Manual*. Large sections are subject to modifications of carbon content only to a range of 0.10 (10 points); see page 24 of *Manual* 10.

Phosphorus and Sulfur Limits. When basic electric furnace steel is specified, phosphorus and sulfur limits are to be 0.025% max each; for basic open-hearth steel 0.040% max each; for acid open-hearth or electric steel 0.050% max each. (These elements not used in computing hardenability.)

† For basic steel. Lowest minimum silicon limit to be specified for acid steel is 0.15%.

‡ Sulfur 0.040 to 0.060%.

§ Supposedly none. Residual assume 0.10–0.25.

‖ Ditto. Assumed 0.05–0.10.

¶ Ditto. Assumed 0.00–0.08.

** NE9400 series, as established Aug. 17, 1942, had high silicon (0.40–0.60%), and low nickel and chromium (0.20 to 0.40% each). Silicon, nickel, and chromium were dropped to their present range on Aug. 15, 1943. Also take prefix A.

* *Permissible Chemical Variations.* Phosphorus and sulfur in open-hearth steel to be 0.040% maximum each. Phosphorus and sulfur in electric furnace steel to be 0.025% maximum each.

Small quantities of certain elements may be found in alloy steel which are not specified or required. These elements are to be considered as incidental and acceptable to the following maximum amounts: copper 0.35%, nickel 0.25%, chromium 0.20%, molybdenum 0.06%.

The chemical ranges and limits shown are subject to the standard permissible variations for check analysis over the maximum limit or under the minimum limit. These permissible variations are: 0.01 for all ranges of carbon; 0.03 for manganese up to and including 0.90%, and 0.04 for over 0.90 to 1.55% inclusive; 0.005 for either phosphorus or sulfur; 0.02 for silicon; 0.03 for nickel up to and including 1.00%, 0.05 for nickel over 1.00 up to and including 2.00%, and 0.07 over 2.00 up to and including 5.30%; 0.03 for chromium up to 0.90% inclusive, and 0.05 for chromium over 0.90 to 1.75% inclusive; 0.01 for molybdenum up to 0.20% inclusive, 0.02 for molybdenum over 0.20 to 0.30% inclusive.

Quality Conditions. All conditions and quality features, except as detailed above, shall be in accordance with the regulation, shown in the American Iron and Steel Institute's *Steel Products Manual*, Section 10 on alloy steels.

NOTE. NE denotes National Emergency Standard Steel.

4. PRESENTATION OF DATA

LIMITATIONS. Appreciation of the limitations of conventional mechanical tests and of the importance of properties not, or not easily, measurable in quantitative figures, plus appreciation of the similarities among fully quenched, quenched, and tempered steels, leads to abandonment of the effort to express in figures properties not so expressible for direct use in design.

The indirect connotations implied, but not measured, by conventional mechanical tests still have some value if their indirectness and their frequent inaccuracy are kept in mind, and so some such values will still be given. But primary attention will be given to listing groups of ferrous materials available to the designer, with running comment on advantages and disadvantages, whether these can be put in figures or must be only qualitatively described.

CLASSES OF FERROUS MATERIALS FOR ENGINEERING DESIGN. Broad classifications of ferrous materials of construction are *cast* and *wrought*, with further subdivisions as to method of manufacture and intended processing and use; *duplex* materials; and the catch-all class of *special* materials.

5. CAST IRON AND MALLEABLE IRON

The selection of iron-base cast metals is not handicapped by many chemical requirements imposed by official specifications. Classification is on the basis of mechanical properties, the foundryman being left free to use his experience and judgment in adjusting composition. Cast materials in general are free from the directional differences in properties characteristic of most wrought materials. They are size-sensitive and demand suitable initial design to facilitate gating and feeding for soundness and experienced foundry technique to insure soundness. Consultation with patternmaker and foundryman before freezing a design tends to insure sounder castings, lower production costs, and less scrap both in foundry and machine shop.

GRAY CAST IRON (see also Section 19). This metal is easy to cast sound, very readily machinable, not ordinarily considered weldable, and incapable of cold forming. It is evaluated on tensile strength or transverse strength; it has no yield point but displays a curved stress-strain diagram. It is relatively brittle; its approach toward toughness is evaluated by special impact tests on unnotched bars. Hardness is not necessarily a direct reflection of strength.

Composition. Gray iron has a matrix of silicon-bearing iron in which are embedded graphite flakes. The silicon-ferrite matrix may be accompanied by pearlite particles, that is, by iron carbide in layer formation, as in steel, or the matrix may be all pearlite. Hardness rises and machinability decreases as the matrix structure approaches all pearlite. The softer irons have higher carbon, the range being about 3.25 to 3.75%, with silicon at about 1.50 to 2.50%, strong irons near 3% carbon, silicon lower, sometimes down to 1%. The balance among carbon, silicon, manganese, sulfur, phosphorus, and any alloying elements and the use of various inoculating ladle treatments for graphite control depend on the strength desired in the section to be cast, the type of casting, and the sort of matrix wanted. Graphite size and distribution play a very large part. Composition should not be specified but should be left for the foundryman to fit to the particular case in hand. The higher the silicon and carbon, the softer the iron, and the larger the graphite flakes. The foundryman balances the carbon and silicon to suit the casting to be made. Strength depends more on shape and distribution of graphite than on its amount. Composition is not the sole regulator of strength; melting practice and addition of "modifiers" are factors. Structure is altered by variations in rate of freezing. Rapidly chilled corners may be white, very hard, and brittle.

Tests. The strength of a given composition varies with the section cast. Transverse and tensile tests should be made on specimens of like section to that of the casting. Conventional sizes are 0.875, 1.2, and 2.0 in. diameter. Transverse tests are often used for foundry control; tensile, for design data.

Mechanical Properties. Interrelations among the various mechanical properties have been discussed in detail (Ref. 16). Modulus of elasticity varies with strength, weakest irons being about 12 million psi, strongest about 19 million. Damping capacity, ability to absorb energy without transmitting it, is high, decreasing with increased strength. Torsional strength runs 1.2 to 1.4 times tensile strength, compressive strength is about $3\,{}^1/_2$ to $4\,{}^1/_2$ times tensile strength, making gray iron highly useful against compressive loading. Machinability decreases as strength increases but remains relatively high.

Endurance limit, unnotched, runs $\frac{1}{3}$ to $\frac{1}{2}$ tensile strength. Notched endurance is equal to unnotched in weakest irons, only moderately reduced in strong irons. Even under corrosion fatigue, in fresh water at least, notched specimens have relatively long life for a ferrous material of such strength. (See also Section 19, Article 2, Iron and Steel Casting.)

Specifications. Commercial gray irons are classified according to minimum tensile strength, pounds per square inch. ASTM specifications A48-46 cover the following grades: 20,000, 25,000, 30,000, 35,000, 40,000, 50,000, and 60,000 tensile irons. (See Section 19, Article 2.) Specifications A159-44T for automotive castings cover 20,000, 30,000, 35,000, 40,000, and 45,000 tensile irons. (See Section 19, Article 2.)

Specific gravity rises from about 7 to 7.7 as strength increases. Irons up to and somewhat above 40,000 psi tensile are widely available commercially. Higher-strength irons are more difficult to produce, especially in large sizes, and less easily controlled for soundness. Irons for some special purposes can be supplied if the use is clearly described.

Temperature Effects. The properties of gray iron are not widely different at subnormal temperatures or at elevated temperatures, up to around 600 F, but above that ordinary cast iron is subject to oxidation "growth" and consequent deterioration. Slight chromium additions stabilize the carbide and avoid growth to temperatures where oxidation resistance is insufficient for service. The linear coefficient of thermal expansion of cast iron is lower than that of steel, varying from around 0.000005 to around 0.00001 per degree F with class of iron and temperature range. The thermal conductivity likewise varies but is of the same order as that of most steels.

Wear resistance of gray iron is a function of the type of service and of the structure of the iron.

Alloying. The 40,000 psi tensile irons may be, and higher-strength irons, especially for large sections, usually are, alloyed. The alloying elements are much the same as those used in steel, and, as in steel, various elements and various combinations may be used interchangeably. Most cast irons are made in the cupola; the very-high-strength and the alloyed irons, which normally carry less carbon, are often made in electric or air furnaces.

Heat treatment of cast iron is not carried out to improve properties as a structural material but may be useful in respect to wear resistance. Surface hardening by flame or induction can be applied to produce a hard, wear-resisting surface.

Stress Relief. As in any casting, internal stresses may be present which, if not relieved, may cause warpage on machining. In earlier days iron castings were allowed to "season" for long periods at atmospheric temperature, which provided some slow and slight stress relief. A stress relief anneal at 800 to 1050 F for a few hours, followed by slow cooling, relieves these stresses without affecting mechanical properties.

Casting. Most gray iron castings are made in sand. Pipe is often made by centrifugal casting, which may result in a thin outer skin of chilled iron, which is graphitized and softened by heat treatment. Gray iron is seldom cast to extremely precise dimensions, since it is so easily machined. However, small castings can be made to close dimensions by casting in permanent metal molds, using a soft iron, and coating the molds to avoid chilling the edges and surfaces.

NODULAR CAST IRON. A new material of construction which has interesting potentialities is a variety of cast iron with much the same properties as pearlitic malleable (p. 2-34). By treatment of the melt with *cerium*, as in the product developed in England by the British Cast Iron Research Association, or with *magnesium* (added as a rather low magnesium content alloy with copper or nickel), as in that developed in the United States, the iron can be made to freeze with its graphite in the nodular form familiar in malleable iron, without requiring the more or less lengthy heat treatment required in the various varieties of malleable.

The ductility and toughness obtained with the nodular rather than the flake graphite structure give the as-cast nodular iron a combination of properties such as 60,000 psi yield, 100,000 psi tensile, and around 5% elongation, the properties, of course, shifting with section size. By heating for one hour at 1650 F, then slowly cooling, the properties become of the order of 50,000 psi yield, 75,000 psi tensile, and 20% elongation (Refs. 50 and 51).

While it remains for simulated service tests and actual use to demonstrate just what such ductilities imply, as to service toughness, the structure and properties are so similar to some of the malleables as to imply suitability for uses heretofore open to malleable but closed to ordinary cast iron. A considerable amount of experience and know-how will be required to insure obtaining the correct structure, so some time may elapse before the material becomes widely available.

WHITE AND CHILLED IRON. Cast iron of suitable composition may be gray, i.e., with a gray fracture from the presence of much graphite, when cooled slowly during freezing, but may be white, with fracture practically free from graphite, when more rapidly cooled, as when cast against a metal chill which abstracts heat more rapidly than a sand mold. The white, chilled face is very hard and brittle but wear resistant. It contains internal stress which needs to be relieved by heat treatment.

Wearing portions of a gray cast-iron camshaft are often chilled on their working faces, but little structural use is made of castings that are white throughout, because they are too brittle. However, sand-blast nozzles and castings for a few analagous uses are exceptions.

White iron upon wearing portions, such as plow points and railway car wheels, supported by less brittle material, meets a need in services where the chilled layer is not subjected to tensile stress. Such castings, notably car wheels with chilled running faces, are subjected to a heat treatment reminiscent of a "full anneal" of steel, to alter structure somewhat and relieve internal stress.

Inasmuch as the foundry adjusts the chemical composition of castings with chilled surfaces to meet the particular conditions, the user should not specify composition.

Completely white iron, chilled throughout, is the starting point for the production of malleable cast iron.

MALLEABLE CAST IRON. By long heat treatment of white iron at sufficiently high temperature, graphite, usually called "temper carbon," is deposited in tiny, rounded clumps, or nodules, much smaller and more uniformly distributed than the graphite of gray iron, leaving the matrix silicon-containing ferrite (ordinarily around 1% silicon) almost carbon free. The carbon content of malleable ranges from about 1.75 up to around 3%, i.e., lower than in gray iron. The silicon hardens the ferrite and makes it less gummy on machining than low-silicon ferrite. The temper carbon nodules make the chips break up and prevent welding of the chip to the tool. Fully malleabilized iron is the most easily machined of all ferrous products. (See also Section 19, Articles 9, 10, 11, and 12.)

Specification. Malleable is an exception among ferrous products in that increased strength is usually accompanied by increased rather than decreased ductility and toughness. ASTM specification A47-33 covers two grades, and A197-39 covers cupola malleable.

ASTM No.	Tensile Strength, psi min	Yield Strength, psi min	Elongation, in 2 in., % min	Specific Gravity
32510	50,000	32,500	10	7.25–7.35
35018	53,000	35,000	18	7.20–7.45
Cupola	40,000	30,000	5	7.10–7.20

Higher strengths and elongations are frequently produced in all these. For example, some manufacturers will supply 33,000 psi minimum yield, 12 1/2% minimum elongation. The two higher-strength grades are produced in the open hearth, air furnace, or electric furnace, since to secure these properties the carbon content needs to be lower than is readily obtainable from the cupola.

The grade with 10% elongation has usually been considered adequate for automotive uses. The 5% elongation grade, cupola malleable, is widely used for pipe fittings. "Toughness" as measured by Charpy keyhole notch specimens runs about 7, 6 1/2, and 5 ft-lb, respectively, for 32510, 35018, and cupola grades, but wider differences and more toughness for the first two grades than the figures would ordinarily be taken to indicate are shown by the "wedge curl" test. A bend test also demonstrates toughness and the ability of malleable to be cold formed. As Rehder (Ref. 17) points out, elongation in the tensile test is no sure criterion of bending toughness.

Special-alloy malleable iron can be produced with 60,000 psi tensile, 40,000 psi yield, 18% elongation; 65,000, 54,000, and 14% have been reported for precipitation-hardened copper-alloyed malleable.

The endurance limit, determined on unnotched specimens, runs close to one-half the tensile strength. Scanty notched endurance data indicate rather better behavior for malleable than for cast steel of equal yield strength. The elastic modulus runs from 20 to 26 million psi.

Temperature Effects. Up to around 600 F the elevated temperature properties do not depart greatly from those at room temperature, and good behavior in creep up to 775 F has been reported. At low temperature, notched-bar and wedge-curl values may be slightly depreciated or may drop not far below room-temperature values. When information on low-temperature behavior is wanted, the particular lot to be evaluated should be tested.

Malleable iron is sometimes zinc coated by the hot-dip process, and the necessary temperature may or may not produce some embrittlement. Means are known for avoiding this, as by prior heat treatment. Cupola malleable is not prone to galvanizing embrittlement.

treatment which the producer may choose, sets no chemical limits beyond the conventional 0.06% sulfur, 0.05% phosphorus, and classifies the steels solely on mechanical properties, for which minima are specified as in Table 11, Article 5, Section 19.

The polished- and notched-bar fatigue behavior can be approximated from Fig. 2. Behavior of Grade B steel in single-blow notched-bar impact tests at room and lower temperatures has been described by Sims and Dahle (Ref. 21), who show that the deoxidation practice has a major influence. When such behavior is to be appraised, tests need to be made on each heat, unless it is known that proper deoxidation practice will always be applied.

Foundry Practice. The foundryman is free to adjust carbon content, grain-size control, and alloy content to the heat treatment chosen. He will ordinarily prefer so to alloy as to secure the specified properties by normalizing or normalizing and drawing, and for the 50,000 and 60,000 psi yield strength classes the foundryman usually chooses "intermediate manganese steels" with around 0.33% carbon and $1\frac{1}{2}$ and $1\frac{3}{4}$% manganese respectively. If other elements are present, from scrap, which help make austenite sluggish and thus allow normalizing to a fine, strong structure, he reduces the manganese accordingly. However, normal manganese and a wide variety of other elements, singly or with small amounts of several, give equivalent results.

Ductility. The 90-60 grade was earlier known as "Grade C," for which the specification, now replaced by A148-46T, required 90,000 psi tensile, 60,000 psi yield, 22% elongation, 45% R.A., instead of the 20% and 40% now required. That is, a steel with 21% and 42%, rejected in purchasing on the old specification becomes acceptable on the present one. From this example it is evident that ductility specifications are not really sacred. A good many heats of 60,000 psi yield will show 26% elongation and 60% R.A. It would take a lot of proving to demonstrate that such heats are any better for service than those with 20 and 40%, especially when it is noted that the ductility required for grades 80-40 and 105-85, admitted to be respectable constructional materials, is still lower. The ductilities stated are merely those that accompany ordinary compositions, heat treated in the ordinary way, to a given yield strength.

Yield Strength. The grades of higher yield strength are obtainable by quenching and tempering of low-alloy compositions, the amount of alloy increasing as higher yield strengths are desired. There are "hard" grades of carbon and of alloy cast steels in which carbon may go up, but rarely above 0.50%, when wear resistance is wanted and weldability, machinability, and toughness are relatively unimportant. The higher carbon content is ordinarily steered clear of, especially when the steel is to be quenched.

Cast carbon and alloy steels can be quenched and tempered to yield strengths closely corresponding to those obtainable in the same steels when wrought, but, since castings are often complex and unsymmetrical with thick and thin portions, it has been considered hazardous to quench them for fear of quenching cracks. However, experience with quenching of huge castings for Army tanks, which were alternatively used with parts fabricated from plate by riveting or welding, proves that, with proper design and skilled control of heat treatment, supposedly unquenchable castings behave nicely.

At equal yield strengths, castings will not show as high ductility as wrought products, rolled or forged, tested in the direction of working, but this is compensated for or more than compensated for by the casting having like ductilities in all directions.

Size Effects. It is necessary to remember that the mechanical properties of steel castings are conventionally determined on separately cast specimens 1 in. by 1 in. in cross section, very adequately fed by a huge riser. There is a strong size effect in steel castings; very thin sections will have higher properties, heavy ones, in their interiors, appreciably lower ones. Center unsoundness may be marked, especially in large, flat castings, and, of course, when quenching and tempering are applied, if hardenability is insufficient to avoid slack quenching, the tiny specimen, quenched and tempered, is as unrepresentative of the interior of the casting as a small wrought-steel specimen.

CASTING DESIGN. Honest sampling of a casting from the actual heat of steel, from the full section, with its actual heat treatment, is imperative for sound design. Even such sampling, unless it hits an unsound spot, does not insure that the casting, as a structure, may not be unreliable because of gas holes, shrinkage cavities, or other interior defects. These defects are avoidable, with decent foundry practice, if the design allows proper feeding and escape of gas. A heavy section cannot be fed through a light one that freezes first, nor can gas bubbles escape through the frozen portion. Incompletely fed heavy sections inevitably contain shrinkage cavities or spongy metal. Chills on heavy sections help to approach more uniform freezing but are seldom completely effective.

The designer must do his part by straining every nerve to avoid unequal sections, to provide good fillets, to avoid sharp angles at which cracks may start from cooling stresses, and to allow the patternmaker so to construct the pattern that the foundryman can use proper gates and risers. He should check with both of them in time to alter the design to meet their needs. If the requirements for making a sound casting are not met in a proposed design, and the design cannot be modified to meet them, then the structure should be subdivided into parts that can be cast.

These elementary precautions are needed in all the cast ferrous products, whether gray, malleable, or pearlitic malleable irons, or cast steel.

These precautions for getting sound castings and detailed discussion of many features of cast ferrous metals, as well as the classes of products for which each type has been successfully applied, are given in the *Cast Metals Handbook*, published by the American Foundrymen's Association, 222 West Adams Street, Chicago, Illinois.

One final feature about castings should be mentioned. If a small amount of a special tailor-made iron or steel, not readily available in the market, is needed for a particular, special use, it can easily be supplied as a casting, or as stock for forging, by foundries having suitable metallurgical know-how and small electric furnaces. Such foundries can render service that steel mills or foundries equipped only with large furnaces cannot.

A relatively unexplored possibility for saving is by use of a casting, made nearly to final size, as a forging blank, to reduce the number of expensive forging dies and operations.

7. WROUGHT IRONS AND PLAIN CARBON STEELS

IRONS AND STEELS NOT INTENDED FOR HEAT TREATMENT. Many objects may be fabricated by cold bending, deep drawing, spinning, or a variety of other ways of securing plastic deformation, into final shape, or into subshapes thereafter joined mechanically or by welding, brazing, soldering, etc. They may be painted, metal-coated, or coated with vitreous enamel. Formability is often the prime requisite, the final object being designed more for stiffness than for strength, and that stiffness being normally accompanied by ample strength for the conditions of service, even when made from the weakest of steels. Very thin stock can be more easily deformed than thick and, if properly protected against corrosion, often serves. When thin stock does not supply the required stiffness or strength, heavier stock, still of weak steel, will often be chosen, unless weight considerations are important.

Plastic deformation hardens and embrittles iron or steel, and at some stage in such deformation a condition may be reached where any further attempt at deformation would produce a crack. In such a case, deformation is stopped short of that stage, and the steel is returned to approximately its original soft and ductile condition either by a "process anneal," carried out at a temperature at which the steel matrix remains ferritic, or, more rarely, by a "full anneal" carried out by heating far enough for the steel to become austenitic. With stronger grades of steel or with sections of weak ones so heavy that they will stand too little cold deformation without cracking, the steel may have to be heated and deformed while still hot.

Processing. Some purposes require nothing but formability; others may superimpose requirements for weldability, suitability for vitreous enameling, or the like. Irons and steels very low in carbon meet formability, weldability, and various other requirements more readily than steel with higher carbon. Very-low-carbon steels are more cheaply produced rimmed or semi-killed instead of fully killed. The still lower carbon exterior of rimmed steels has the advantage of a better surface for deep drawing, but such steels, unless properly killed and their grain size controlled, are subject to "stretcher straining," to surface markings, and to a precipitation-hardening type of "aging embrittlement" by which a steel, easily formable when freshly rolled, cracks during forming after this embrittlement has progressed with time.

Attempts to specify utility in indirect terms of chemical composition and conventional mechanical properties fall far short of adequate evaluation of the thin stock under discussion. Such materials, however, are in wide demand and are in quantity production by all steel mills, which, consequently, have evolved processing methods resulting in suitability for specific types of further processing by the purchaser, though the degree of suitability may be unmeasurable save by putting the material through this actual further processing. Yet the supplier, fully informed as to the use to be made, can often correlate his own practice with good and bad behavior in the user's hands.

Unless the user has similar knowledge and can devise some simple test proved to be applicable to his own case, he does better to order in terms of the fully described use and final processing methods than to resort to published specifications, if such exist, or to try to build up a specification, assumed to be applicable, on the basis of conventional tests.

THIN STOCK. Thus there is no virtue, and would be considerable danger, in a handbook listing of properties of low-carbon steels in thin stock which might, by inference, be interpreted as suitable data on which to build a purchase specification. Purchase specifications exist for thin stock where mechanical properties come into consideration and structural purposes are intended, but they do not purport to indicate directly anything about suitability for processing, and specific statements are contained in ASTM Specifications to this effect.

Rolling Practice. In earlier practice, thin gages were hot rolled singly down to, say, $^1/_{16}$ in. thick, then pack rolled hot, and finally box annealed for a long time at around 1200 F. More economical production first hot rolls as before. Further reduction, however, is by cold rolling in continuous mills, then either a long box annealing of coils or a short normalizing heat treatment at about 1700 F in a continuous furnace is employed for softening prior to difficult cold forming. The cold-rolled strip, hard from its cold rolling, may be process annealed for times and temperatures which only partly soften it, leaving it stronger but less amenable to cold forming by the user.

ASTM Specifications A246-44T (for material under 0.05 in. thick) and A245-44T (for 0.05 in. to 0.25 in.) cover open-hearth and acid Bessemer steels and set the following chemical maxima:

	Carbon, %	Phosphorus, %	Sulfur, %
Open-hearth	.25	.06	.05
Bessemer	.11	.11	.06

When "copper-bearing" steel is ordered, for resistance to atmospheric corrosion, 0.20% minimum copper is required.

For material under 0.05 in. the mechanical requirements are:

	Tensile	Yield	Elongation in 2 in., %	Bend, without Cracking
Commercial grade	*	*	*	Flat in any direction, then doubled flat in opposite direction
Grade A	45,000	25,000	25	Flat in any direction
Grade B	50,000	30,000	23	180° in any direction over its own thickness
Grade C	52,000	33,000	18 †	In longitudinal direction only, over 1 1/2 times its thickness

* Commercial grade is subject to bend test only.

† Sliding scale, lower as thickness decreases.

For the heavier stock, up to $^1/_4$ in. thick, the requirements are:

	Tensile	Yield	Elongation in 2 in., %	Elongation in 8 in., %	Bend, without Cracking
Commercial grade	*	*	*	*	Requirements for each grade same as for thin stock, above
Grade A	48,000	25,000	23	29	
Grade B	52,000	30,000	20	25	
Grade C	55,000	33,000	18	22	

* Commercial grade is subject to bend test only.

Carbon will seldom be at the 0.25% maximum in commercially available material. The lower carbon in Bessemer reflects the strengthening effect of the phosphorus content of Bessemer, requiring that carbon be lower than in open-hearth in order to retain the desired formability. All tensile specimens for both thickness ranges are taken in the longitudinal direction.

HEAVIER STRUCTURAL STEEL (HOT-ROLLED). A blanket specification for ordinary hot-rolled plates, shapes, and bars is ASTM A7-46. They are to contain 0.20% copper when ordered copper-bearing. Material $^7/_{16}$ in. and under may be Bessemer or open-hearth or electric, heavier stock only the last two.

Carbon limits are not specified, but carbon content is to be reported to the purchaser. In Bessemer, phosphorus is 0.10% maximum, no sulfur limit stated. Phosphorus in acid open-hearth or electric is 0.06%, in basic 0.04% maximum. Sulfur is 0.05% maximum. No limitation is stated as to killing; rimmed, semikilled, or killed are all permissible, nor are grain-size limitations set.

Strength requirements are: tensile 60,000 to 72,000 psi (upper limit set in interest of formability); yield, half the tensile strength but not below 33,000 psi; elongation in 2 in., 22% minimum; elongation in 8 in., 1 $^1/_2$ million divided by tensile strength, this requirement being reduced for material over $^3/_4$ in. or under $^5/_{16}$ in. thick.

Cold-bend requirements for plates, shapes, and bars are 180° without cracking over a pin whose diameter bears the following relation to thickness of material:

Thickness, in.	Ratio of Pin Diameter to Thickness
3/4 and under	1/2
3/4 to 1	1
Over 1 to 1 1/2	1 1/2
Over 1 1/2 to 2	2 1/2
Over 2	3

All this sums up to the fact that commercial hot-rolled carbon steel has low yield strength, which ranges from 25,000 to 36,000 psi. Ductility and formability, as indicated by elongation and bend, vary with thickness, the usual expectations as to what degree of these goes along with the yield strength being expressed by the specification figures.

INGOT AND ENAMELING IRONS. Implied in some ASTM specifications, a low-carbon rimmed material, usually under 0.04%, called ingot iron is commercially produced. A typical analysis of this material is 0.015% carbon, 0.025% manganese, 0.005% phosphorus, 0.025% sulfur, and trace of silicon.

Ingot iron * is a commercially pure iron made by the basic open-hearth process. Tensile strength ranges from 38,000 to 48,000 psi, and yield point from 18,000 to 32,000 psi, depending on the processing, with elongation as high as 48% in 2 in. for the dead soft material. Endurance limit in reversed bending is 26,000 psi for annealed rods or plates, impact is 90 ft-lb (longitudinal) and 56.3 ft-lb (transverse) on the Izod scale for normalized material, and Brinell hardness ranges from 67 to 220. Magnetic and electrical properties of ingot iron make it especially suitable for direct-current applications. If ingot iron for such uses is processed by any form of mechanical working the magnetic properties, except permeability at high inductions, are impaired and must be restored by suitable annealing. The relatively low electrical resistance of ingot iron as compared with steel has led to its use in telegraph wire and bond wire for rail signal circuits and as a third rail for electric railways. High magnetic permeability and low retentivity have stimulated its use for a wide range of magnetic applications. In sheet form ingot iron is extensively used for porcelain enameling.

Because of its high ductility ingot iron can be severely cold formed. In hot working there is a critical range from 1580 to 1920 F, due to low manganese content, which must be avoided. The high ductility and extreme toughness make it necessary to employ special tool shapes in cutting (see Section 23). Both plates and welding wire of ingot iron possess good characteristics for gas, arc, and resistance welding. Slightly higher heat is used than for steel because of the higher melting point of ingot iron. Rivets of ingot iron up to 3/8 in. in diameter may be driven cold.

ASTM specification A129-46, Open Hearth Iron Plates of Flange Quality, covers ingot iron under the designation Type A, for which tensile strength is given as 44,000 psi, yield point 27,500 psi, and elongation 25% in 8 in. ASTM specifications A178-46, Electric Resistance Welded Steel and Open Hearth Iron Boiler Tubes, and A83-46, Lap Welded and Seamless Steel and Lap Welded Iron Boiler Tubes, cover ingot iron under the designation Type B, Open Hearth Iron. (See also Refs. 53 and 54.)

Special enameling irons are also commercially available. One of them carries a high titanium content, sufficient to combine the already low carbon content as titanium carbide instead of iron carbide, leaving the matrix practically pure ferrite with inert titanium carbide inclusions, the idea being to avoid iron carbide which can react with oxides of the enamel during firing of the enamel to produce carbon monoxide gas and hence blisters.

The relatively pure iron matrix has a high critical temperature, in the absence of iron carbide, and remains in the ferritic condition at usual enamel firing temperatures, thus being stiffer and sagging less than when the austenitic condition is produced. Higher critical temperature and resistance to sagging are also met in low-carbon, high-phosphorus enameling irons.

WROUGHT IRON is a low-carbon, high-phosphorus material very high in intentional slag content. It used to be made by laborious hand processes, but is produced now by intermingling overblown, low-carbon Bessemer steel with molten slag to form a conglomerate which is worked down to the same structure as the older product.

The slag, rolled down into plates and stringers, produces highly directional properties and low transverse ductility, but when wrought iron is broken across the grain it fractures woodily, much as would a laminated pack of plates.

Wrought iron is readily weldable. Depending on section, its longitudinal tensile strength runs from 45,000 to 48,000 psi, yield strength 22,500 to 29,000 psi, longitudinal ductility high, transverse ductility very low. Several ASTM specifications exist for a variety of wrought-iron products. Claims for corrosion resistance of both ingot iron and wrought iron in comparison with steel, have been made, not all of which have been borne out. All these low-carbon materials are lower in strength than ordinary structural steel.

---

* Data furnished by Armco Steel Corp., Reid L. Kenyon, associate director, research laboratories.

COLD-WORKED CARBON STEEL, THIN SECTIONS. Yield strength can be increased by cold work—cold rolling for flat stock or cold drawing for wire, bar stock, and tubes.

Specification. Cold-rolled strip steel, open-hearth or electric, 1/4 in. or under in thickness, is covered by ASTM A109-38. Material not required to take more than slight bending may contain up to 0.25% carbon. Otherwise, the chemical limits are carbon 0.04 to 0.12, manganese 0.30 to 0.60, phosphorus 0.04 maximum, sulfur 0.05% maximum. As to mechanical properties, bend tests only are required.

Temper. The cold-rolled stock is described and ordered by the vague term "temper" in five grades: 1, hard; 2, half-hard; 3, quarter-hard; 4, soft; and 5, dead-soft tempers. No bend requirement is imposed for hard (No. 1) grade. No. 2 is to bend to a sharp right angle across the grain, No. 3 flat on itself across the grain, to a sharp right angle along the grain, No. 4 and No. 5, flat on themselves both ways of the grain.

Mechanical properties, expected but not specified, are:

	Rockwell B Hardness	Tensile, psi	Elongation* in 2 in., %
No. 1	84–96	68,000–92,000	1– 5
No. 2	75–85	56,000–72,000	4–14
No. 3	64–74	48,000–60,000	13–27
No. 4	52-64	43,000–53,000	24–36
No. 5	38–52	40,000–48,000	33–45

* Elongation values for material 0.05 in. thick. Elongation varies with thickness.

Yield strength, not included in the ASTM discussion, will vary according to thickness of stock and the way the tensile strength has been produced, i.e., whether by a very light reduction, or by a severe reduction followed by process annealing and how far the softening by process annealing has been allowed to progress.

With the elongation measured on stock 0.03 in. or thicker, one producer gives the following relations, longitudinal specimens:

Tensile, psi	Yield, psi	Elongation in 2 in., %, minimum
40,000	25,000	35
45,000	40,000	28
54,000	50,000	20
82,000	80,000	5

Transverse and longitudinal tensile properties cited by this producer do not vary noticeably. Compressive yield strength is quite close to tensile yield strength.

In the bending or forming of hot-rolled stock, or of soft-temper cold-rolled, very severely deformed portions acquire hardness and mechanical properties akin to those of hard cold-rolled stock; by suitable heat treatment those portions may be softened, just as in the soft tempers of cold-rolled stock.

High Strength. By starting with steel of higher carbon content and giving it severe cold reduction, much higher strength can be obtained. Spring wire, hard drawn, is covered by ASTM 227-41 and music spring wire by A228-41. They require killed steel. The other chemical requirements are:

	C, %	Mn, %	Si, %	P, %	S, %
227–41	0.45–0.75	0.60–1.20	0.10–0.30	0.045 max	0.05 max
228–41	0.70–1.00	0.20–0.60	0.12–0.30	0.03 max	0.03 max

Tensile strength runs as follows:

ASTM	Diameter, in.	Tensile Strength, psi
227-41	.032	275,000–310,000
	.500	165,000–195,000
228-41	.004	390,000–440,000
	.156	255,000–285,000

Intermediate sizes have intermediate strengths. The stress-strain diagrams for heavily cold-worked steels are curved because of internal stress. Tempering at around 400 F straightens out the diagram and gives a yield strength around 90 to 95% of the tensile strength. Strength can be lowered and ductility increased by regulated process anneals.

Wire of around 0.80% carbon previously heat-treated to give it a structure suitable for cold drawing, then cold-drawn, is used in bridge suspension cables. In wire of 0.192 in. diameter, this material shows around 220,000 psi tensile, 183,000 yield, around 6% elongation in 10 in., and about 40% reduction of area.

HOT-ROLLED CARBON-STEEL BARS. In hot-rolled carbon steels, strength depends primarily upon the amount of pearlite, that is, upon carbon content. Increase in manganese content, within the limits accepted by the definition of carbon steels, also increases strength. The amount of hot reduction, the finishing temperature at which rolling is stopped, the grain size, and the section size (which controls the rate of cooling after hot rolling) also exert influence.

AISI 1000 Series. Readily available commercial hot-rolled carbon steels are those included in the AISI 1000 series. The median carbon content, from which deviation of a few points is permitted, varying from a total range of 0.05% carbon in the lower carbon steels, up to 0.15% in the highest, is denoted by the last two digits of the assigned number. Thus, for example, 1040 covers 0.37 to 0.44% carbon. With a few exceptions the lower carbon steels, through 1025, carry 0.30 to 0.60% manganese (1016 carries 0.60 to 0.90% and 1019 and 1022 carry 0.70 to 1.00%). Steels 1030 through 1080 carry 0.60 to 0.90% manganese, whereas 1095 carries 0.30 to 0.50%. Steels 1008 through 1020 are rimmed or semikilled, whereas 1025 to 1095 are killed, with silicon running 0.10 to 0.30%. Phosphorus is 0.04 and sulfur 0.05% maximum.

The steels may be had as hot-rolled, or "cold-finished," or cold-drawn. The properties of the cold-drawn stock will depend on the degree of cold reduction and the stress-relief heating that is applied. This treatment is ordinarily given by the producer, rather than the user. "Typical" longitudinal tensile values for cold-finished bars of about 1 in. diameter are cited in ASTM Specification A108-46, for information only. Typical values, also for information only, for hot-rolled bars about 1 in. in diameter are given in ASTM A107-46. Combining these:

AISI	Hot-rolled 1-in. Bars			Cold-finished 1-in. Bars		
	Tensile, 1000 psi	Yield, 1000 psi	Elongation in 2 in., %	Tensile, 1000 psi	Yield, 1000 psi	Elongation in 2 in., %
1008	50	26	40	58	48	18
1010	54	27		60	50	16
1015	58	29		65	55	15
1016	64	36		68	58	14
1019	....	....		70	60	14
1020	62	34	35	68	58	14
1022	69	41		72	62	13
1025	65	37		72	62	13
1030	78	42		80	70	12
1035	83	45		85	75	12
1040	89	48	25	90	80	12
1045	95	52		95	85	10
1050	100	56		100	90	8
1055	104	59	15	....	....	....
1060	108	62		....	....	....
1070	120	68		....	....	....
1080	125	72	10	....	....	....
1095	135	78	6	130	115	4

NOTE: Longitudinal elongation values for hot-rolled are not included in ASTM table. Values have been spotted in from figures given by Sisco (Ref. 22). Intermediate compositions have intermediate values. As Sisco shows, transverse elongation values on comparable plate are lower, sometimes only half as large as the longitudinal. Directional differences are often even more marked in the cold-finished steels.

A plain carbon Bessemer steel, B1010, in which carbon is held to 0.13%, phosphorus 0.07 to 0.12%, sulfur 0.06% maximum, and manganese 0.30 to 0.60% shows: Hot-rolled, 63,000 psi tensile, 36,000 psi yield; cold-finished, 65,000 psi tensile, 55,000 psi yield, and 12% elongation.

Yield strengths ranging from around 25,000 to around 75,000 psi for the range of compositions in hot-rolled are increased from around 50,000 to 100,000 psi, with appreciable ductility still retained, by cold finishing. Cold-finished flats up to 6 in. in width and rounds, squares, and hexagons are available. Shafting is cold finished up to 8 in. in diameter.

Free-machining steels and steels higher in manganese than the above are supplied both hot-rolled and cold-drawn. Some of them are included in ASTM A107-46 and A108-46. They will be mentioned later under alloy steels.

Flange Quality. Hot-rolled structural iron or carbon steel plates are supplied for uses requiring a higher degree of formability than that of everyday structural steel, for example, "flange quality," ASTM A129-46, which calls for 44,000 psi tensile, 27,500 psi yield, 25% elongation in 8 in. longitudinal values for stock 3/4 in. thick.

Flange and firebox plates A285-46 come in three grades, with 0.80% maximum manganese, and carbon ranging from 0.15 to 0.30%, depending upon grade and thickness of plate. The three grades have 50,000, 55,000, and 60,000 psi tensile, each one ±5000 psi; yield strength half the tensile, with 24,000, 27,000, and 30,000 psi respectively as minima; and elongation in 3/4-in. plate equal to 1,550,000 divided by tensile strength, with usual modifications for other thicknesses. These grades are for welding, and need not be killed. They must withstand a more severe bend test than that of ordinary structural A7-46.

Steel for locomotives and cars A113-46 includes much the same range of properties displayed by the range covered by the three grades of steel just mentioned. Again, no silicon content is specified, the steel does not have to be killed, only to meet the mechanical properties.

Higher mechanical properties are produced in steels which have been given the misnomer "carbon silicon" steel. The strength is not due to silicon, but rather to high carbon and manganese. One of these, "structural silicon steel," which has been used in riveted structures but in which the maximum carbon (0.40%) in ASTM A94-46 is too high for easy welding, has 80,000 to 95,000 psi tensile and 45,000 psi minimum yield and is required to stand the usual ductility and bend test requirements. Grades intended for fusion welding, restricted to lower carbon and 0.80% maximum manganese (A201-46), have 55,000 to 65,000 psi and 60,000 to 70,000 psi tensile; yield, half the tensile; and the usual other requirements.

Stronger plates, up to 4 1/2 in. thick, with higher carbon and up to 0.90% manganese permitted (A212-46) give 65,000 to 77,000 psi and 70,000 to 82,000 psi tensile ranges, yield half the tensile. Another specification (A284-46T), for plates over 2 in. thick, to be welded, calls for 0.80% manganese maximum, 0.31 and 0.35% carbon maximum, in two grades having 55,000 and 60,000 psi tensile, 27,500 and 30,000 psi yield minimum, respectively.

In all these silicon is required, a range of 0.15 to 0.30% being set except in A94-46, where 0.20% minimum is called for. That is, these are killed steels.

From the design point of view, the steels in each of the different grades, when of equal yield strength, behave pretty much alike, save that differences in manner of killing will be detectable in low-temperature behavior, and differences in grain size in high-temperature behavior, which the conventional acceptance tests do not cover. The gradations relate to formability and weldability—to processing—not to serviceability in final use. Steel mills charge different "extras," according to the formability required. They appraise the formability more on the basis of their knowledge of how a heat was processed than on conventional mechanical tests.

Ship steel takes one of the highest "extras." A steel in which no silicon requirement is stated, and carbon and manganese are unrestricted, but a maximum tensile is set in the interest of formability is "structural steel for ships," running 60,000 to 70,000 psi tensile, yield half the tensile but not less than 33,000 psi, elongation varying with thickness but not less than 22%. Since this steel does not have to be killed, its low-temperature behavior depends on degree of killing actually employed. Failures in welded ships made from steel complying with this specification testify that meeting a specification drawn in terms of conventional tensile and bend tests is no complete assurance that it is exactly fitted for a particular use. Although revised in 1946, the ASTM specification makes no mention of ship failures.

In all the grades of steel mentioned above, the degrees of weldability and formability required are accompanied by low yield strength. Designers often require a considerable degree of each of these in steel of distinctly higher yield strength. In plain carbon steel, raising the carbon enough to reach this higher yield strength level sacrifices too much in these properties. Hence, alloying of low carbon steels is resorted to, when a combination is needed. Of course, when strength only is called for, high carbon steel can be used, as in rails, ASTM Specification A1-46 and A2-27, where different carbon ranges within 0.55 to 0.90%, with relatively high manganese and silicon sufficient to kill, are used. Drop tests are imposed in A1-46 and a "Giant Brinell" test in A2-27. For use as concrete reinforcement, steels of 33,000 to 50,000 psi yield are covered by specifications A15-39, A16-35, A160-39, A184-37 and cold-drawn wire of 64,000 psi yield by A82-34.

Rerolled rails, analogous to A16-35, expected to show 50,000 psi yield are commercially available in shapes small enough to be rolled from sections obtained from used rails by cutting the head and base from the web. When formability, toughness, and weldability are not required, such material is available to the designer.

8. MILD-ALLOY OR HIGH-YIELD-STRENGTH LOW-ALLOY STEELS

LOW-ALLOY STRUCTURAL STEEL. A blanket specification, A242-46, covering material 3/16 to 2 in. thick, sets a carbon maximum of 0.20% and a manganese maximum of 1.25%, with no restriction on phosphorus or on alloying elements other than manganese; it is intended, however, that alloying elements be used that increase resistance to atmospheric corrosion. The size effect is recognized by the following gradations:

Size, in.	Tensile, psi	Yield, psi	Elongation in 8 in., %
3/16– 3/4	70,000	50,000	1,500,000 divided by tensile, with deductions for material under 5/16 in. or over 3/4 in.
3/4 –1 1/2	66,000	45,000	
1 1/2 –2	63,000	40,000	

Cold-bend requirements: Bend 180° over a pin whose diameter is given by the following:

Plate thickness	3/16–3/4 in.	3/4–1 in.	1–1 1/2 in.	1 1/2–2 in.
Ratio $\frac{\text{pin diameter}}{\text{plate thickness}}$	1	1 1/2	2	2 1/2

The steel is intended to be suitable for welding. It does not have to be killed, but usually is.

BOILER PLATE. Certain steels with about 40,000 psi minimum yield up to nearly 50,000 maximum (37,000 to 43,000 psi minimum, in the case of A202-46, up to 55,000 maximum) for plates for boilers and other pressure vessels are listed by ASTM with chemical limits superimposed on mechanical requirements under A202-46 (chromium, manganese, silicon); A203-46 (nickel steel); A204-46 (molybdenum steels); A225-46 (manganese vanadium).

Wider use is made of steels of more complex composition designed to give, in the welding grade, 50,000 psi yield in 1/4 in. thickness, and 55,000 or even up to 60,000 to 70,000 psi in the grade for riveting. Around 25 to 35% elongation in 2 in. accompanies the 50,000 psi yield strength. In each grade it is usually feasible to achieve the 50,000 or 55,000 psi yield in stock considerably thicker than 1/4 in. by suitably adjusting the alloy content. Grain-size control and finishing practice are influential in maintaining the desired yield strength.

"VANITY" STEEL, low-carbon, high-manganese, with tiny additions of either vanadium or titanium, usually both, whence the name, has received much attention for high-strength ship plate (Ref. 23). Copper, for atmospheric corrosion resistance as well as for strength, is usually present in rather generous amount. Phosphorus also confers corrosion resistance, and is a potent strengthener. If the sum of carbon plus phosphorus is too high (0.25% total is around the practical limit), toughness is reduced. But phosphorus does not injure weldability, as too high carbon does.

Killed Bessemer steel, which has been much used for pipe, of around 0.15% carbon, 0.10% phosphorus, 0.50% manganese, 0.20% silicon, aluminum-treated, has 45,000 to 55,000 psi yield strength, 25 to 35% elongation in 2 in.

Hence, two types of this class of steel, with indistinguishable room temperature mechanical properties, are made, one with medium carbon and low phosphorus, the other with very low carbon and relatively high phosphorus.

Characteristic compositions (sulfur, ordinarily 0.02 to 0.03%) are given in Table 6.

Table 6

	C	P	Mn	Si	Cu	Ni	Cr	Mo	V	Ti	Al	Zn
Vanity	.16	.02	1.20	.25	.20 *	.15 *	.03 *	.02 *	.05	.015	.015	...
	.09	.10	1.20	.55	.45	....	...	.25	...	....	....	.
	.10	.10	.60	...	.60	.60	...	.20		....	...	...
	.10	.08	.60	.10	.60	.85	...	...	...	.06	...	...
	.13	.02	.70	.80	.20	.20	.60	...	...	....	....	.12
	.11	.02	.75	...	.80	1.00	..	.10		..	...	.
	.08	.02	.50	.25	1.00	1.60	...	...	...	..	...	.
	.10	.12	1.10	.05	.35	...	.			..	.....	
	.10	.10	.60	.15	1.10	.55	..			....	...	
	.10	.10	.25	.75	.40	.50	.75		..	...	...	..
	.10	.10	.75	.30	.50	.50	.75	...	..	..	.	.

* Residuals.

For the present at least, all such steels carry the same price extra. Each of the major steel producers makes a steel of this class. Each maker, through experience with his pet composition, may be able to produce that steel in better quality than one he is not used to.

From the user point of view, the steels appear interchangeable. Possibly the low-temperature behavior of the high phosphorus may not be up to that of the low phosphorus, although properly deoxidized heats of the phosphorus class show excellent behavior.

RIVETING GRADE 55,000 TO 65,000 PSI YIELD STRENGTH. When weldability is not required and formability is less important, yield strength of as-rolled mild alloy steels can be raised, either by raising the carbon or raising the alloy. Such steels can be welded if proper welding technique, usually including preheating and postheating (stress-relief anneal) can be applied, but they are not as foolproof as the "welding grade." In the high phosphorus group the carbon is not raised, but the alloy content is, a dash of molybdenum being especially effective.

One of the earliest steels in this yield strength range was a killed 0.30% carbon, 1.50% manganese, 0.20% copper steel. A steel of similar composition but with carbon lower, around 0.20 to 0.25%, and with about 0.15 to 0.17% vanadium added, is suitable for normalizing, even in decidedly large sections. To secure the highest yield strength, normalizing from a temperature at which grain growth does not occur is applied rather than leaving the steels of this group in the as-rolled condition, since heating to rolling temperature may produce too coarse a grain.

In the high phosphorus group there is a steel of 0.17% carbon, 0.09% phosphorus, 1.00% manganese, 1.00% copper plus nickel, and 0.20% molybdenum.

Steel of around 0.25% carbon or a bit under, with manganese at around 0.90%, plus silicon and copper each at about 0.50%, with nickel and chromium each approaching 0.25%, also falls in this yield strength category, an example of using small amounts of several elements.

Other examples of cutting manganese down a bit from the 1 1/2 level and using other alloys to add the desired strength are:

Carbon, %	Manganese, %	Silicon, %	Copper, %	Chromium, %	Nickel, %	Molybdenum, %
0.20	1.25	0.75	0.20	0.50	....	....
0.25 *	1.00	0.25	1.40	....	0.90	0.25
0.22	0.80	0.25	0.95	....	1.90	....

* Yield strength at this carbon level about 70,000 psi.

At 55,000 yield, the riveting class will have about 25 to 30% elongation in 2 in., dropping to around 15% at 70,000 psi.

FORMABLE 75,000 PSI YIELD STRENGTH STEEL. As has been previously stated, by using a high copper content, forming prior to reheating, then reheating for precipitation hardening, mild alloy steels of fairly low carbon can be raised to 75,000 psi yield.

The factor that gives mild alloy steels their high yield strength is the sluggishness conferred by the alloy content upon austenite, by virtue of which its transformation to ferrite and pearlite is held back to occur, upon air cooling, at a lower temperature and with resultant finer structure than in steel with negligible alloy content.

NE NORMALIZING STEELS. By increasing the cooling rate, as by quenching, this transformation can be avoided and quench-hardening induced, if the austenite is sufficiently sluggish. Hence this class merges into that of the "shallow-hardening" steels, which could equally well be classed as "deep-normalizing" steels. Since their air-cooled structure will contain bainite and they contain internal stress, the deep-normalizing steels need tempering.

Properties. Stewart and Wiley (Ref. 24) studied a large group of the NE steels, those containing enough silicon, 0.20 to 0.35%, for killing, and alloying amounts of manganese (0.85 to 1.40%), chromium, nickel, each in the neighborhood of 0.50%, and molybdenum at about 0.25%, at 0.30 to 0.55% carbon normalized in 1 in. and 8 in. round, and tempered at various temperatures.

In 1-in. section, yield strengths ranging from 65,000 psi at the 0.30% carbon end tempered at 1200 F to 100,000 psi at 0.45% carbon tempered somewhat lower, with corresponding elongation of 30 and 20%, were obtained. The yield strength is, of course, lower for a given hardness and tensile strength than would be obtained by martensitic quenching and tempering back to that hardness.

In 8-in. section, Stewart and Wiley determined both longitudinal and transverse tensile, Charpy notched-bar, and endurance limit on longitudinal smooth unnotched specimens. Even in this large section, yield strengths of 50,000 to 55,000 psi were obtained at the 0.30% carbon level and a high tempering temperature and 60,000 to 80,000 psi at the 0.45% level, depending upon alloy content and tempering temperature. The transverse yield strength equaled the longitudinal, but the usual directional differences were met in ductility and notched-bar behavior.

Application. These molybdenum-containing, deep-normalizing steels, although designed for quenching and tempering in relatively small sizes, offer interesting possibilities as engineering materials for large normalized sections. While not all the NE steels studied by Stewart and Wiley remain in regular production, the steels initially classed as NE and now included as regular AISI steels are readily available and, with adjustment of carbon content and tempering temperature, will cover the range of yield strengths shown by the group studied.

The variety of alloy compositions in the mild alloy and NE low-alloy groups, applicable for strengthening a base steel of a given carbon content and with mechanical properties indistinguishable at the same carbon content and same hardness, is evidence that the combination of alloying elements used to make austenite sluggish and produce the proper structure is immaterial. The structure and properties result almost exclusively from the sluggishness, not from the alloy combination, even though, because of its potency, molybdenum is used in the NE steels as cap stone of the alloy structure. Molybdenum-free compositions could readily be substituted.

Hence, instead of considering that he should specify some particular alloy composition, the designer might well ask for normalizing steel on the basis of the carbon level and the yield strength needed in a given section, and let the alloy chips fall where they may.

9. FREE-MACHINING STEELS

The free-machining behavior of steel results from its structure. The structure may be somewhat controlled by heat treatment further altered by introducing "foreign material" which forms a new structural constituent in the matrix, and by modification of the matrix itself.

The idea that softness makes for easy machining and hardness for difficult machining is only partly true. Pure ferrite or structures with much ferrite uninterrupted by harder constituents are gummy and stick to the tool, producing a rough, torn finish. After the chip is separated from the work piece, the chip has to be disposed of and kept from clogging the spaces between teeth of a multi-tipped tool. Turning is therefore one thing; broaching, sawing, etc., another.

Machinability is variously evaluated, sometimes primarily on the surface left, especially in finishing cuts, sometimes on energy required to remove a cubic inch of metal, especially in hogging cuts, and frequently on the tool wear life between grinds. What the tool will stand, i.e., whether it is carbon, high-speed or carbide, its angles, the rigidity of the machine setup, etc., have as much to do with the dividing line between machinable and unmachinable as the material cut. Hence no blanket definition of, and no single conventional test for, machinability can be drawn up.

Qualitatively, machinability is enhanced by having enough carbon, say 0.20%, to supply pearlite patches sufficient to break up the continuity of the ferrite matrix. With lower carbon content, raising phosphorus (as in the mild alloy steels) stiffens the matrix and makes it less gummy. For hogging cuts coarse grain size facilitates machining, but it leaves a rougher surface under a finishing cut than fine grain.

Heat Treatment. In medium-carbon steels, heat treatment leaving a lamellar pearlite structure is usually advised for milling, drilling, and broaching, and a spheroidized structure for turning, though in the higher carbon steels the latter may not be the better. In very-high-carbon steels, the spheroidized structure may be required for most types of machining.

Since the structure and grain size can be controlled by heat treatment, it is often advisable to give a preliminary treatment to produce the structure needed for the particular type of machining to be done, then machine, leaving stock for a light finishing cut, then reheat-treat to produce the structure wanted for yield strength, and take the finishing cut.

Thus the designer can rely on the heat treater to mitigate relatively poor machining properties of steels for uses where mechanical properties are paramount and cost of machining a minor factor.

Sulfide Inclusions. When yield strength is the chief design need and other mechanical properties, especially toughness and fatigue resistance, are not material, machinability can be greatly enhanced by raising the sulfur content, and the manganese content along with it, to supply manganese sulfide inclusions to break up the continuity of the ferrite matrix and produce short chips. Such additions may be accompanied by high phosphorus to stiffen the ferrite matrix. Selenium can be used instead of sulfur; it is more common in austenitic stainless steels than in ordinary constructional steels. Bismuth or lead may also be used in the austenitics.

These sulfide inclusions lead to great directional differences in toughness and fatigue behavior as has been discussed on p. 2-04.

In steels for quenching and tempering, where an extreme of these directional effects would be hazardous at the strength level desired, a compromise is often made by just raising the sulfur content a point or so above the "maximum" sulfur restriction of the conventional specification.

Lead. One method of materially raising machinability without introducing appreciable directional effects or loss of toughness, even in quenched and tempered steels at high hardness levels, is by introduction of lead, analogous to making brass more free machining by microscopically visible lead globules.

In steel, 0.05 to 0.20% lead greatly improves machinability and, probably because the lead particles in steel are too small to be found microscopically, save perhaps by very special technique, the mechanical properties are practically unaltered in any direction. In England, large amounts of lead-alloyed steels were used during World War II, even in projectiles at high hardness where no loss in toughness could be tolerated. The leaded steels are produced only on special order in the United States at present.

Silver is insoluble in solid steel, just as lead is, and small silver additions are sometimes made to die-block steels where the final tooling is at high hardness. Machinability is improved without impairing mechanical properties. The silver-treated steels, also, are specialty products.

Molybdenum. The statement is often made that quenched and tempered steels high in molybdenum machine appreciably better at rather high hardness than comparable steels without it.

SPECIFICATION. The conventional free-machining carbon steel bar stocks, for use where decreased toughness and fatigue resistance can be borne, are described in ASTM A107-46 for hot-rolled and A108-46 for cold-drawn. Cold-drawn is commonly used in automatic screw machines because of closer dimensional tolerance achieved by cold drawing.

Bessemer. Of these the Bessemer (high-phosphorus) steels with high sulfur are considered the easiest machining, B1113 standing at the top:

					Longitudinal Specimens				
					Hot-rolled		Cold-drawn		
AISI No.	C, %	Mn, %	P, %	S, %	Yield, min	Tensile, ave	Yield, ave	Tensile, ave	Elongation in 2 in., %
B1010	0.15 max	0.30–0.60	0.07–0.12	0.06 max	36,000	63,000	55,000	65,000	12
B1011	0.08–0.13	0.70–1.00	0.07–0.12	0.10–0.15	40,000	65,000	55,000	75,000	10
B1112	0.08–0.13	0.70–1.00	0.07–0.12	0.16–0.23	40,000	65,000	55,000	75,000	10
B1113	0.08–0.13	0.70–1.00	0.07–0.12	0.24–0.33	40,000	65,000	55,000	75,000	10

Open-hearth steels, all with phosphorus 0.045% maximum, are:

				Longitudinal Specimens				
				Hot-rolled		Cold-drawn		
AISI No.	C, %	Mn, %	S, %	Yield, psi	Tensile, psi	Yield, psi	Tensile, psi	Elongation in 2 in., %
1115	0.13–0.18	0.70–1.00	0.10–0.15	35,000	62,000	55,000	65,000	16
1117	0.14–0.20	1.00–1.30	0.08–0.13	41,000	68,000	60,000	70,000	15
1118	0.14–0.20	1.30–1.60	0.08–0.13	43,000	70,000	65,000	75,000	14
1120	0.18–0.23	0.70–1.00	0.08–0.13	36,000	66,000	......	....	..
1137	0.32–0.39	1.35–1.65	0.08–0.13	55,000	95,000	80,000	90,000	10
1141	0.37–0.45	1.35–1.65	0.08–0.13	60,000	100,000	85,000	95,000	10
1151	0.48–0.55	0.70–1.00	0.08–0.13	65,000	110,000	90,000	105,000	8

Numbers 1115 to 1120 are usually unkilled, and are mainly used for carburizing; 1137 to 1151 usually carry silicon for killing. The 1137 to 1151 steels are amenable to quenching and tempering.

Cold-drawn 1337, stress-relieved, ranges on longitudinal tests from 100,000 psi tensile, 80,000 psi yield, 15% elongation, 45% reduction in 1/2 in. diameter, to 90,000 psi, 70,000 psi, 15%, 45% in 2 in. and 85,000 psi, 65,000 psi, 12%, 35% in 3 in. If especially heavy drafts are taken in cold drawing, as Landis (Ref. 25) explains, these values are somewhat improved. It is to be remembered that, unlike the center of a quenched and tempered shallow-hardening steel, the centers of the cold-drawn bars have properties closely similar to those of the periphery.

Many analogies will be seen between this group and the mild alloy and low alloy previously discussed. In the Bessemer group, the usual carbon plus phosphorus limit is not exceeded. In the open-hearth group, the as-rolled strength increases as either carbon or manganese rises, and at the highest carbon level, in 1151, manganese drops in order to retain some toughness.

Open-hearth steels with higher than the 0.13% maximum sulfur can also be obtained, for example, modified 1144 with 0.20 to 0.32% sulfur.

It will be noted that yield strength is a function of carbon, phosphorus, and manganese, and is not altered by raising sulfur even to around 0.30%.

Not mentioned in the ASTM specifications cited is 8640, with sulfur at 0.07% maximum, for a combination of ability to secure the usual mechanical properties without great directionality, yet with improved machinability, as is pointed out by Boyer (Ref. 26), who rates it, cold drawn, as of excellent machinability. His argument for a specific method of adding sulfur to open-hearth steel probably finds little general agreement, but his listing of relative machinability of quite a group of steels probably would find general agreement. He also lists the "extras" obtaining at the date of the article.

It is generally considered that cold drawing adds materially to machinability, but for some types of machining, at least, this belief has been challenged.

GRAPHITIC STEELS. Another free-machining steel starts its career in much the same "white-iron" condition as pearlitic malleable, but its composition is so balanced that the material can be hot rolled, or forged from the ingot without appreciable graphitization. Upon slow cooling, however, a process applied by the manufacturer, graphite or temper carbon separates out. Such steels contain around 1 to 1 1/2% carbon and up to around 1% silicon, with less silicon when another graphitizing element such as aluminum is present. The slow cooling causes something like half the carbon to separate as tiny graphite nodules, leaving a matrix of pearlite and silico-ferrite which is heat treatable. Depending upon the temperature and time of austenitization, very little or quite a proportion of the separated graphite can be taken back into solution, so the effective carbon content of the matrix can be controlled.

Hardenability. The austenitized matrix, carrying graphite "inclusions," can be quenched and tempered. The matrix of one grade has about the same composition as one of the tough, oil-hardening tool steels. The matrix can be made shallow hardening even in water, by omitting elements that promote hardenability, keeping the silicon low, and adding about 0.15% aluminum. With higher silicon a more deeply hardening, water-hardening steel is produced. With a little molybdenum on top of higher silicon, a still more deeply hardening, oil-hardening steel results. Tungsten, which produces harder carbide, is added in special wear-resistant uses. Piling in silicon, manganese, nickel, molybdenum, and chromium produces an air-hardening steel.

In all the modifications the separated graphite nodules provide remarkably easy machining at relative high hardness. Like all high-silicon steels, these are prone to surface decarburization and need care in heat treatment to avoid it.

The tensile and yield strengths of the matrix, if fully quenched to martensite and then tempered, bear the same relation to each other as holds in all fully quenched and tempered steels; they follow the master plots of Figs. 8 and 9. Ductility is, of course, reduced by the graphite particles, but since these particles are produced after rolling, and uniformly distributed, directional differences are less than in steels made free machining by manganese sulfide.

Lubricant. The graphite particles appear to serve as receptacles to retain oil lubricant, as well as to supply lubricating effects from graphite itself. These effects result in long-wearing punches and dies.

Yield strengths in the quenched and tempered condition can be varied, by adjustment of composition and tempering temperature from 100,000 to 175,000 psi or, for wear-resistant purposes, to the order of 225,000 psi.

Application. The graphitic steels are commercially available. Although they are used primarily as wear-resistant punches and the like, cams and slide ways are applications in ordinary design. For a complex machining job that needs to be done at unusually high hardness, even where only structural strength is required, without wear resistance, they are worth keeping in mind.

10. ALLOY CONSTRUCTIONAL STEELS FOR QUENCHING AND TEMPERING

In earlier handbooks, alloy constructional steels were viewed as distinct entities, plots of tensile properties against tempering temperature, or analogous tables, being given for each of the steels then designated by SAE numbers, and lists of products for which each steel was frequently used were often included. Without statement of the section size of the particular product, such lists are meaningless.

Properties. As discussed earlier, property charts, based on sections which harden fully to martensite, can be condensed into the master plots of Figs. 8 and 9. The properties of the interior of a section which does not harden to martensite throughout, after tempering of the nonmartensitic core along with the martensitic outer zone, depend upon the size of the section, which controls the rate of cooling, as well as upon the sluggishness of the austenite. Yield strength and other properties grade down, in a sufficiently large section, from those moderately inferior to the surface properties to the distinctly inferior properties of a normalized steel, as the center is approached.

Design. The designer may generalize the problem by determining to what depth a fully martensitic quenched outer layer is needed, to what yield strength and accompanying toughness this layer should be tempered back, and what strength is needed in the underlying material to support this outer layer.

Quenched hardness of the initially martensitic outer layer is determined by its carbon content. The lower the carbon, the less the danger of cracking an unbalanced section upon quenching, but the more alloy is required to produce deep hardening.

Past experience or analogy with other examples indicates what depth of hardening and what carbon level are suitable for the case in hand, and similar experience tells whether water can be used or whether oil quenching is required to avoid quench cracking. The steel that has fitted these requirements in the past has probably been chosen with considerable excess average hardenability, secured at the expense of costly total alloy content to insure this hardenability at the lowest carbon and alloy levels permitted by the earlier specification for that steel, based on chemical composition.

Hardenability Specification. If the Jominy hardenability curve for that steel at this low chemical level is determined, that curve can be matched with the lower boundary of the Jominy hardenability band of one or more of the cheaper, less heavily alloyed, steels now available as "H," i.e., controlled hardenability steels. This procedure automatically matches the carbon levels but does not imply the same alloy content. Parker (Ref. 14) shows the closer hardenability limits of some of the 8600, 4100, and 4600 series of steels when ordered as "H" steels instead of by composition, and discusses the matching of the Jominy values to the section to be treated.

The economics of selection on a hardenability basis and of considering price in choosing among steels of like hardenability has been interestingly discussed by Brown (Ref. 27). Any such steel, tempered back to the same surface hardness as was used for the satisfactory more highly alloyed steel, has a high degree of probability for showing identical service. Thus the 8600, 8700, and 9400 series, with controlled hardenability, are rapidly replacing the 2300, 3100, 4100, 4600, and 6100, even the 4300 series. A few of the many published statements attesting to such replacements are listed in References 26 to 33.

Compositions. Tables 2 to 5 summarize the compositions of the steels in the AISI list. In order to secure optimum yield strengths, the steels, especially above 0.20% carbon, are usually specified to be fine grained.

The wide hardenability bands for the various AISI numbered steels when ordered merely to the chemical composition ranges for those numbers and the narrower ones for the controlled hardenability "H" steels are available in pamphlets published by the AISI (Ref. 12). A few examples are given in Figs. 12 and 13.

Carbon content for steels to be quenched ranges from 0.20 to 0.55% and total alloy content from not much over 1% up to around 5%. With low-carbon and low-alloy content the steels are shallow hardening and can be water quenched; with both carbon and alloy content high, they are deep hardening and require oil quenching. Steels high in carbon and so highly alloyed as to be hardenable on air cooling in small or medium sections are not ordinarily applied to constructional uses.

Condensed information on sizes hardening in oil or water with carbon from 0.20 to 0.50% for the 8600 series to whatever hardness is selected, and the relation of the hardness gradients to the conventional Jominy curve, are contained in Boegehold's plot (Fig. 14).

Steels with higher than 0.55% carbon occur in the plain carbon 1000 series; they are used for cutting tools not expected to operate at high temperature, for wear-resistant purposes, in railway rails, and in small springs.

Steels of the 52100 series, with carbon at around 1% and chromium up to 1 1/2%, are used for ball and roller bearings and races; 6195, with about 1% each of carbon and chromium plus about 0.20% vanadium, and steels with 0.50 to 0.65% carbon, about 3/4% manganese and about 2% silicon, as well as 8650, are used for springs of fairly heavy sections.

11. STEELS FOR CASE HARDENING

CARBURIZING. Two general classes of steels are used for carburizing: first, those of 0.10 to 0.20%, second, those of around 0.30 to 0.35% carbon, each with or without alloying elements.

Case Depth. Low-carbon steels are ordinarily given a thick case, thick enough to withstand crushing by virtue of its own strength in spite of being underlain by a very soft core. Higher carbon steels may be given a relatively thin case since it is adequately supported by the harder core.

The hard, brittle, high-carbon case is applied for wear resistance. In the vast majority of uses the thin case is thick enough to provide for all permissible removal of metal by wear, and the chief reason for a thick case is to allow grinding tolerance upon a warped piece, so that a sufficient case thickness still remains. It would be better to avoid warping and save the time and expense of applying the thick case.

Thick cases are usually applied by heating the pieces for a long time along with a solid carburizing agent, thin ones more commonly for a much shorter time in a gaseous carburizing medium. In either case, heat treatment is applied after carburizing, the heat treatment involving at least a quench to produce martensite in the case, followed by a low-temperature tempering to "toughen the case" without materially softening it, leaving it file-hard. In spite of this "toughening," the case is always brittle. Case toughness is sometimes demanded to allow straightening a warped piece without cracking the case. It is very doubtful if much straightening can really be done without cracking the case, although the crack may not be visible and the case, though cracked, may still adhere to the core.

The case may have only about 0.80% carbon, or it may run up to well over 1%. Alloy steels containing strong carbide-forming elements such as chromium or molybdenum may be used to provide more wear-resistant carbides, but they tend to build up a higher carbon content on the surface than is desired, and a steeper carbon gradient. Even when the surface carbon is not very high, whatever the steel composition, appreciable time must be allowed for diffusion of carbon into the core so as not to have a sharp line of demarcation between high carbon case and lower carbon core, but instead a gradual gradient, in order to avoid spalling of the case.

This diffusion time means that, despite differences in the rate at which the extreme surface picks up carbon in different alloy steels, the time required for producing a given depth of a proper type of case and diffusion zone does not vary greatly, though the presence of high manganese appears somewhat beneficial.

Core properties have received much misapplied attention. Because the case is brittle anyway, it has been supposed that the core should have extreme toughness; hence the very low carbon of the steels that were first used, in spite of their gumminess and poor machinability. The toughness of the core used to be evaluated on "pseudo-carburized" stock that was put through the whole heat treatment cycle, but without carburizing agents, or on the core after the case had been removed. But when engineers became curious enough to study the carburized piece as a whole (Refs. 34, 35), as it is used in service, it turned out that impact values, either notched or unnotched, are highly variable, but low. That is, a crack once formed in the brittle case propagates readily even through a core that behaves tough when the case is removed.

The behavior of the case can be studied by making a bend test of a carburized specimen, noting the deflection at which a "ping," from the development of a crack, is heard. The case behavior, which depends upon the carbon content, the carbon gradient, and the thickness of the case, is determined by the carburizing technique but very little affected by the steel composition. Few uses of carburized parts admit enough deflection to crack the case, and for gears, Almen and Boegehold concluded that impact test figures did not correlate with service behavior.

Automobile tire chains are in an unusual category in that the case serves only to delay initial wear, the core being exposed for a large part of the life.

As long as the toughness of the core was regarded as having meaning in respect to service, great pains were taken to alloy and heat-treat the steel to obtain the aimed-at core properties. Since the low-carbon core becomes austenitic only at high temperature whereas the high-carbon case becomes so at much lower temperature, a double quench was used. A high-temperature quench was used to refine the core, followed by reheating to a lower temperature, at which the case becomes austenitic but the core does not, then again quenching to harden the case.

The core refinement was applied because, in the long sojourn at carburizing temperature, excessive grain growth occurs in steels that coarsen easily. Use of grain-control agents to produce fine-grained steels avoids this trouble.

Steels Used. There is danger of warpage, even of cracking the case, every time the part is quenched, to say nothing of the cost of the extra operation. For this reason, the use of fine-grained steels and a single quench for case properties, with less regard for the alleged need of core toughness, is the general rule. Low-alloy steels serve, and very little use is made of the very highly alloyed ones, such as the 1 1/2% chromium, 4% nickel steels that were favored for maximum core toughness. Boyer (Ref. 26) remarks that

8617 and 8620 are almost the only alloy steels now in wide use for carburizing, 1019 being preferable among plain carbon steels for deep carburizing.

A growing tendency appears for the use of higher carbon steels, 0.30 to 0.35% and a thin, gas-carburized case upon this stronger core. A still thinner hard case, containing both carbide and nitride, can be applied by use of molten salt baths containing cyanide. Here the core is often made still harder, for adequate support, and steels of 0.35 to 0.45% carbon are utilized. With heat treatment applied only for case properties, the core properties approach those of a normalized steel as previously described.

SURFACE HARDENING. When a very thin hard surface will serve and minimum distortion is needed, carburizing is omitted, and a still higher carbon steel chosen for support. This is first heat treated to secure the desired strength, then the skin only heated and quenched. Automatic devices for flame hardening and for induction hardening have come into wide use. The steel is usually plain carbon of about 0.45% carbon, or a very mildly alloyed steel, since no ability for depth hardening is required. The processes are very rapid, the equipment fits readily into a production line, and there is no need for expensive steels.

NITRIDING. A supremely hard and wear-resistant, but very thin, case is produced by a long low-temperature treatment (below the austenitic range), in ammonia, of steels alloyed with elements that readily form nitrides, notably aluminum, chromium, molybdenum, and vanadium. The steel, usually of 0.25 to 0.40% carbon, must first be quenched and tempered, machined or ground free from any decarburized surface, nitrided and the nitrided surface preferably lightly ground to remove a very small part of the thin nitrided layer, since the outer film is not so hard as the underlying material and more liable to spall. Moreover, this can be made to compensate for the very tiny increase in dimensions.

The nitrided layer is brittle and nitrided pieces cannot be straightened, but warpage is at a minimum. Half a dozen compositions of nitriding steel are commercially available. Their price is high, since they contain 2 or 3% of alloys, and the process is long and costly. The hardness is retained at high temperatures that would materially soften a quenched, carburized case.

The nitriding steels quench and temper to much the usual set of properties shown in the master curves of Figs. 8 and 9. The elongations hug the lower boundary of the band, and the reduction of area values may even be a bit below it, but the variation is not large. From their high alloy content, most of the compositions are deep hardening.

Since fatigue resistance is ordinarily governed by the strength of the surface, the polished-bar fatigue behavior is exceptionally good, and the very hard skin resists scratching. Johnson and Oberg (Ref. 36) obtained over 80,000 psi endurance limit, even when the nitrided layer was scratched. Although nitrided steels are ordinarily employed for wear resistance, they are worth considering for uses where fatigue resistance is paramount.

12. DUPLEX MATERIALS

In a sense, the nitrided, cyanided, or carburized steels are duplex, since their surfaces are of different composition and properties from the interior. Induction or flame-hardened pieces are akin, in having different skin properties, though skin and core have the same composition. Cold working the surface, as by shot-peening, is often highly effective in improving fatigue resistance. Highly undesirable for fatigue resistance is a steel made "duplex" by decarburization of its surface.

CORROSION-RESISTANT COATINGS. Since ordinary steels rust, corrosion-resistant coatings are applied, familiar in tinplate and hot-galvanized or electroplated zinc-coated stock. Steel sheet and strip plated with many other metals are now commercially available, as is hot-dipped aluminum-coated stock. Steel clad with a heavier surface layer, on one or both sides, of copper, nickel, stainless steel, etc., is available in both thin gages and in heavy plate. They are produced by casting the desired coating metal about a steel core and rolling the whole, or by hot rolling the layers together so that they weld.

These materials deserve careful consideration by the designer since they have been developed to the point where quantity production has brought the cost of most of them well below that of a solid piece of the rust- or corrosion-resistant coating metal. The thickness of the coating can be varied according to the intended use and the design strength provided by the steel backing.

"Soft center plow steel," made similarly to clad steel, with a low carbon core and high carbon exterior, thus much like an extremely heavily cased carburized steel, is also procurable. "Sandwich" construction, in which a light, weak, often a porous, nonmetallic backing is faced with strong metal, is very much to the fore in present-day design. The clad steels fit nicely into sandwich assembly. (See Ref. 52.)

SPECIFICATIONS. ASTM Specification A263-44T covers steel plate, sheet and strip clad with corrosion-resisting chromium steel of low carbon content and in different grades from 11½ to 18% chromium, ferritic steel. On sheet and strip a 180-degree cold-bend test is required.

A264-44T covers a similar clad product with the cladding from the group of austenitic corrosion-resistant chromium-nickel alloy steels, and A265-43T, those with the cladding of nickel, nickel-copper, or nickel-chromium-iron alloy.

13. SPECIAL STEELS

The steels previously discussed have been those whose properties depend primarily on the amount and distribution of ferrite and "everyday" carbide and the behavior of ferrite and carbide on heat treatment. Save as the alloy composition serves to make austenite sluggish and thus to control its transformation to ferrite and carbide in the desired state of distribution, the particular alloys in the alloy content have been of very secondary importance except where copper is used for precipitation hardening. The heat treatment of these, except with copper, follows the same general pattern whatever the alloy.

A few steels, mostly high carbon and often highly alloyed, have somewhat special properties because the everyday carbide contains enough of one or more of the carbide-forming elements to modify the carbide somewhat, especially to make it harder. Many tool and die steels come in this category. Since this discussion deals with constructional steels, that class will not be discussed in detail. The carbide in some of the more highly alloyed constructional steels may change in content of the carbide-forming element that replaces iron in cementite, according to the tempering temperature, as discussed by Austin (Ref. 37), but the effect is probably small in the commercial compositions previously discussed.

From the constructional point of view, thermal stability of the carbide allows use of thermally stable carbide-containing steels at elevated temperature. As service temperature goes up, resistance to oxidation is increasingly needed; it is provided by large amounts of chromium, with smaller amounts of aluminum and silicon helping somewhat. Resistance to corrosion, especially by chemicals of an oxidizing nature, is also a characteristic of high-chromium steels.

When the carbon content and the content of carbide-forming elements rise sufficiently, everyday carbide is no longer formed. Instead, a special carbide of different crystallographic form and often of very high hardness appears. Wear resistance and cutting ability may be greatly enhanced by such carbides. The heat treatment required may vary from that for the usual constructional steels.

Large amounts of certain elements and certain combinations of elements make austenite so sluggish that it does not transform, even on drastic quenching, and a class of steels, austenitic at room temperature, results. These steels are necessarily described by chemical composition and must largely be classified in terms of intended use.

HIGH-MANGANESE WEAR-RESISTANT AUSTENITIC (HADFIELD) STEEL. For uses in which heavy battering wear (but not light impact or pure abrasion, as by sand) is involved, steel with 1.0 to 1.4% carbon and 11 to 12% manganese, with or without smaller amounts of other alloying elements, is applied. It is invariably water quenched from 1830 F or higher in order to retain the carbide in solid solution. Regular annealing produces a weak, brittle structure, as does reheating to 650 F or over. The heating and quenching treatment is called a "quench anneal" since this treatment toughens. In the tough condition, the steel starts to yield slightly at rather low loads, but as it deforms, it work-hardens very rapidly, the skin becoming file hard. In wrought stock, in the tough condition, it has around 100,000 to 140,000 psi tensile, 40,000 to 55,000 psi yield with anywhere from 30 to 80% elongation. Machining is extremely difficult because of the work-hardening propensities.

Austenitic steels in general retain toughness at extremely low temperatures, but elevated temperature service of the manganese steel is limited to below 650 F. Hadfield steel is not useful where no change in dimensions of the piece is permissible.

Castings are covered by ASTM A128-33. The only mechanical tests mentioned are a conventional bend test, or the practical one of deforming a casting by pressure or by blows to demonstrate that it is tough and ductile. The cast steel, toughened, has 80,000 to 120,000 psi tensile, 40,000 to 45,000 yield, and 15 to 40% elongation.

A similar steel with lower carbon, the usual manganese plus about 4% nickel, is reasonably tough on ordinary normalizing, without water quenching, and is serviceable at higher temperatures.

TECHNOLOGICAL RESEARCH

HIGH-CARBON, HIGH-CHROMIUM, WEAR-RESISTANT STEEL. For those uses in which wear is combatted by high hardness, steels of about 12% chromium, 1 1/2 to 2 1/4% carbon, often with around 1% molybdenum and 1/4% vanadium, air or oil quenched, find a place. Lathe centers are an example. Such steels are very deep hardening, have low thermal conductivity, require slow heating, careful heat treatment, and avoidance of decarburization. The special carbide present makes them very resistant to tempering, around 58-59 Rockwell C being retained after tempering at 600 F.

PEARLITIC STEELS FOR HIGH-TEMPERATURE SERVICE. Ordinary carbon steels, killed to avoid complications in behavior on elevated temperature aging, drop slowly in yield strength and long-time load-carrying capacity at 650 to 750 F, thereafter more rapidly. For long service at higher temperatures, up to those at which ordinary steels oxidize too rapidly, molybdenum, usually around 0.50%, and a coarse- rather than fine-grained structure are specified. At 1000 F this steel has more than double the load-carrying capacity of plain carbon steel. This is in line with the resistance to tempering of normalized or quenched molybdenum steels, they require higher temperatures for equivalent softening than most other constructional steels. Vanadium also improves high-temperature load-carrying ability in pearlitic steels.

Use of the molybdenum steel, aluminum-killed, in the range of 850 to about 1100 F for several years, resulted in some cases of graphitization and embrittlement. Addition of 1/2 to 1 1/2% chromium materially stabilizes the carbide and prevents or minimizes graphitization. Aluminum killing is avoided when possible; but where it must be used, the chromium is raised from the lower level.

Still higher chromium contents, up to around 9%, are used to add a slowly increasing degree of oxidation and corrosion resistance. Smaller amounts of aluminum and silicon are also employed. A 5% chromium, 0.50% molybdenum composition is in large production.

All these steels ordinarily run in the low carbon range, 0.10 to 0.15%, and are generally used in the normalized condition, for high-temperature steam lines and in the petroleum and chemical industries.

Bolting stock for high temperature use is varied in composition and properties, depending upon the yield-strength requirements and the temperature of service. Since the bolts are usually at a lower temperature than the pipe, heat-treated steels may be used if the operating temperature does not temper the bolt and reduce its initial yield strength too far.

A large variety of ferritic steels with carbon content suitable for quench hardening is in use for bolting stock. The real requirement is a limited stretch or "relaxation" under operating conditions. Relaxation tests are not easy to make, but in these steels the service behavior for the different compositions and treatments are fairly well known by the producer so that the room temperature properties are used for specification purposes. In sizes 2 1/2 in. and under, and tempering at 1000, 1100, or 1200 F, which tempering temperatures are always to be very considerably above the temperature of use, the compositions are chosen so that most of the steels, each after its particular tempering, give 125,000 psi tensile, 105,000 psi yield, 16% elongation in 2 in., 50% reduction of area. Yield strength after tempering at high temperatures is lower in larger sizes.

Pipe. Carbon, carbon-molybdenum, and chromium-molybdenum pipe for high-temperature service are respectively covered by ASTM Specifications A106-46T, A206-46T, and A280-46aT. Some of the steels in the chromium-molybdenum and like alloy steel series for seamless pipe are covered by A158-46T, the bolting materials by A193-46T, and nuts by A194-46. A213-46 covers similar steels for boiler and superheater tubes.

Seamless low-carbon and carbon-molybdenum still tubes come under ASTM A161-46, alloy-steel tubes of these and various grades with chromium under A200-46 and A199-46.

Specifications for castings for fusion welding for high-temperature service are carbon steel, A216-44T, alloy steel, A217-46T. Wrought pipe welding fittings of carbon and carbon-molybdenum steel are covered by A234-44, and carbon-steel wrought pipe flanges and valves by A105-46. They are for high-temperature use.

Castings. Chromium alloy-steel castings, of the ferritic type, are covered by ASTM Specification A221-39 in three classes:

	C, %	Cr, %	Ni, %	Cu, %	Tensile, psi	Yield, psi	Elongation in 2 in., %	R.A., %
A	0.15 max	11.5–14	0.80 max	....	80,000	50,000	20	30
B	0.30 max	17–21	1.00	0.90–1.20	90,000	55,000	5	5
C	0.25–0.50	26–30	3.00	....	55,000	30,000	..	..

Castings with a still wider range of composition, with chromium up to 30%, with different nickel maxima are covered by ASTM A296-46T.

Tubing in the range 11.5 to 28% chromium comes under A268-44T.

Bars. Hot-rolled, cold-finished bars of 11.5 to 18% chromium, with 70,000 tensile, 40,000 yield, 16% elongation, 45% reduction of area are included in A276-44T.

Corrosion Resistance. Some of these steels are discussed and specifications given in the ASME Boiler Construction Code. For general high-temperature service the conditions of oxidation or corrosion have to be carefully considered. These conditions are combatted by chromium, as a mainstay. Other alloying elements are introduced for added resistance to specific types of corrosion, or to permit raising the chromium to the desired level without sacrifice of, or with enhancement of, mechanical properties and workability. For resistance to atmospheric rusting, i.e., to produce a "rustless" or "stainless" steel at least 11 to 12% chromium is required. As the chromium content is raised to around 30%, resistance to severe oxidizing corrosion conditions is increased and resistance to oxidation in air is carried to higher and higher temperatures. The carbon content and the content of other alloys are adjusted to make a steel in which the desired chromium level can be held and the necessary mechanical properties for fabrication and for the particular service contemplated can still be obtained.

Formability. There are limitations to the formability of plain carbon-chromium steels. They are very sensitive to changes in carbon content. Although a carbon steel to be quench hardened contains about 0.25% or more carbon and is all pearlite in the normalized condition, at 0.80% carbon, a steel with 13% chromium quench-hardens (even in air in thin sections) with 0.09% and is all pearlite at 0.30% carbon.

In the "rustless" class, which implies about 13% chromium instead of 18% or more in the "stainless" class, at 0.08 to 0.12% carbon, oil quenched and tempered at 1200 F, a tough product with 100,000 to 120,000 psi tensile, 80,000 to 100,000 psi yield, 20 to 25% elongation, and 60 to 65% reduction of area is obtained and serves for steam turbine buckets and the like. Tempered at 600 F, it runs about 190,000 psi, 180,000 psi, 20%, 60%. For decorative purposes involving cold formability still lower carbon is preferred.

Commercial grades, the 400 AISI series, in the soft, workable condition have about 70,000 psi tensile, 35,000 yield, 25% elongation in 2 in., and can be had ranging from 11½ to 18% chromium. ASTM A176-44 and 240-44 cover solid, A263-44T covers clad plate, sheet and strip in such gradations, designated 403, 410, and 430.

In solid plate sheet and strip higher carbon materials, 442 and 446, with about 0.35% carbon and 18 to 27% chromium, having 75,000 psi tensile, 40,000 psi yield, 20% elongation, are also covered by A176-44. The first fall into the class of "cutlery stainless," which may contain as low as 13% chromium, or as high as 17%, the latter with around 0.70% carbon. After oil quenching, they can, by varying the tempering temperature, have the properties adjusted from 250,000 psi tensile, 200,000 psi yield with low ductility but in the most corrosion-resistant condition, down to around 150,000 psi, 100,000 psi, 10%, 40% in the annealed state. These steels work-harden readily and are difficult to machine, but not so much so as the austenitic types.

At around 16 to 30% chromium, at low carbon content, the chromium steels are ferritic, they do not convert to austenite on heating, and hence are not quench hardenable on cooling. In the lower chromium range, increasing the carbon allows production of austenite, hence quench hardenability. Around 27% chromium the oxidation and corrosion resistances are so excellent that considerable commercial use has been made of such alloys in spite of the fact that if held long in the 750 to 1025 F range, they become excessively brittle upon cooling to room temperature although tough at elevated temperatures. In the annealed state, they are formable unless the previous processing has been such as to create large grain size.

AUSTENITIC STAINLESS STEELS. The addition of carbon, copper, manganese, nickel, and nitrogen to the high-chromium steels tends to make them austenitic. For stainlessness under atmospheric and many corrosive conditions, at least 17% chromium, preferably more, is used, along with varying amounts of the elements just mentioned with a minimum of 7% nickel. The typical composition is 18% Cr, 8% Ni. Some of the nickel can be replaced by manganese, but with complete replacement the chromium cannot be brought up to the desired level and have the steel fully austenitic. Copper is added to improve resistance to certain types of corrosion. Molybdenum is also used for this purpose, and improves high-temperature load-carrying ability as well.

Carbon is held to a low limit in wrought products, especially those to be welded, since a deleterious precipitation effect occurs if the steel is held in the middle of the range 750 to 1500 F or cooled too slowly through it. Carbide precipitates at the grain boundaries which are made more readily subject to chemical attack or to oxidation. With carbon at 0.02 to 0.03%, this does not occur so readily. Such material is now available commercially, avoiding the welding difficulty, but not that of long sojourn in the precipitation range and subsequent exposure to the very active corrodents sometimes used in conventional testing. Such tests may be very misleading. The actual corrodent should be used

Usually the carbon is kept as low as is economically feasible, usually in the range 0.08 to 0.15%, and carbide stabilizers, titanium or columbium, are added when grain boundary precipitation would be met.

Like the austenitic manganese steel, austenitic stainless is "quench-annealed" by rapid cooling from a high temperature and, like it, work-hardens readily and is difficult to machine.

Strength. Since the austenitic steels cannot be hardened by quenching and tempering, strength is imparted by cold working. Properties ranging from those in the soft, formable quench-annealed state of 80,000 to 95,000 psi tensile, 35,000 to 45,000 psi yield, 55 to 60% elongation, 55 to 65% reduction of area can be shifted by cold work to anything between 100,000 psi, 60,000 psi, 50%, 65% up to 300,000 psi, 250,000 psi, 2%, 30%. Even when cold rolled to high yield strength determined by the offset method, there is still a tiny amount of plastic action which makes the stress-strain curve depart a trifle from a straight line even at as low as 24,000 to 30,000 psi, though very much higher stresses are withstood, because of the rapid rate of work hardening, without exceeding a permanent set permissible in most design.

Toughness. The austenitic material is tough, from all points of view, until work hardening has been carried to a great extreme. It is tough in static loading, tough in notched-bar behavior even in large section and at extremely low temperature, and it is outstanding in resistance to notched fatigue. These features make it a useful, though very expensive, material for general construction even when its special properties of resistance to oxidation and corrosion are not required. Its main drawback, other than price, is difficult machinability. Selenium or other additions can be made to improve machinability without greatly depreciating corrosion resistance or mechanical properties.

Appearance. Where decorative appearance is important, as on many parts formed from sheet, a wide variety of finishes ranging from matte to mirror-bright are commercially produced in the sheet itself, the price varying with the finish.

Corrosion Resistance. For increased resistance to certain types of corrosion, addition of up to around 3% molybdenum is made. Digesters, valves, and fittings for the pulp and paper industry make much use of this type. Tabulations of the corrosive conditions combatted by various grades of stainless are available (Ref. 38).

Specification. ASTM A240-44 covers grades of stainless sheet containing molybdenum, columbium, or titanium all with 75,000 psi tensile, 30,000 yield, 30% elongation in 2 in. A167-44 for plate is similar, but requires 40% elongation. A264-44T is for clad steel, and includes coatings of some of these grades.

One specification for 18-8 stainless tubing is A270-44T; that for similar castings is A198-39.

Tubes with 17 to 20% chromium, with various amounts of nickel, and with titanium, columbium, or molybdenum come under ASTM 269-44T.

Cold-worked 18-8 sheet covered by ASTM A177-44 comes in four commercial tempers:

	Tensile, psi	Yield, psi	Elongation in 2 in., %
Quarter hard	125,000	75,000	25
Half hard	150,000	110,000	9 to 10, depending on thickness
Three quarters hard	175,000	135,000	3 to 7, depending on thickness
Full hard	185,000	140,000	3 to 5, depending on thickness

Hot-rolled, cold-finished bars, low carbon (0.08 to 0.10%), of the 18% chromium, 8% nickel type, covered by A276-44T, show 75,000 to 90,000 psi tensile, 30,000 to 45,000 psi yield, 25 to 35% elongation, 45 to 50% R.A. according to size. With 0.15% carbon maximum, the figures are 120,000 to 125,000 psi, 65,000 to 85,000 psi, 12 to 15% and 35% according to size.

Castings of two grades, 0.07 and 0.20% carbon maximum, with 18% or more chromium and 8% or more nickel, both requiring 70,000 psi tensile, 30,000 psi yield, 35% elongation, 40% R.A., are covered by ASTM A198-50. Carbide stabilizers, molybdenum, tungsten, titanium, columbium, or vanadium, and free-machining additions, selenium plus phosphorus or molybdenum plus sulfur, may be made as needed.

ASTM A222-39 deals with castings of higher chromium content:

Class	C, % max	Cr, %	Ni, %	Tensile, psi	Yield, psi	Elongation, %	R.A., %
A	.25 *	22–26	11–13	70,000	45% of tensile	30	30
B	.30	23–27	19–22	72,500	45% of tensile	25	25
C	.30	26–30	8–10 †	85,000	45% of tensile	20	20

* Up to 0.40% for high-temperature use.

† Up to 12% when desired.

Stabilizing elements may be introduced.
ASTM A223-39 covers the high-nickel type:

Class	C, % max	Cr, %	Ni, %	Tensile, psi	Yield, psi	Elongation, %	R.A., %
A	.20 *	8–10	19–22	65,000	30,000	30	35
B	.60	14–17	34–37	60,000	45% of tensile	..	..

* Up to 0.35% for high-temperature use.

A casting alloy of 0.30 to 0.35% carbon around 12% chromium, around 8% nickel, 5% manganese, 2% silicon was introduced as a war substitute (Ref. 39).

Properties. The room-temperature properties merely strive to measure the similarity of a heat to another previous heat whose high-temperature behavior has been studied, and they form no basis for high-temperature design, nor for design for corrosive conditions. The high-temperature behavior of the austenitic high-chromium alloys has been exhaustively studied for load-carrying ability, oxidation resistance in air, and resistance to attack in other atmospheres. One partial study (Ref. 40) of one alloy covers 64 pages. The literature of corrosion resistance of austenitic and ferritic alloy steels is also very extensive.

The way to procure such alloys is to consult the producers, giving all details of the required forming, welding, etc., and complete information on the conditions of service, not only as to temperature of use and its fluctuations, necessary load-carrying ability, permissible deformation and the like but also as to the surrounding atmosphere or, for corrosion-resistant service, like details as to the corrodent. Because design to facilitate production of sound, properly fed castings is highly important, consultation should also be had on this topic.

High-temperature load-carrying ability of the heat-resistant austenitic alloys is much higher than that of the ferritic chromium steels of like chromium level. Alloys for extremely severe high-temperature service are built with sufficient chromium for resistance to oxidation, made austenitic by suitable alloys, usually nickel, and given much increased load-carrying ability by adding several per cent of molybdenum and/or columbium and/or tungsten. The carbon content varies widely. The composition range is sometimes narrow, since a brittle iron-chromium structure, metallographically termed sigma, often tends to appear as chromium is increased above a certain level, a level which varies with the other alloys present.

Still higher load-carrying ability is conferred by large amounts of cobalt. Iron is often reduced so far that the alloys are far from the category of steels.

Blades and rotors for gas turbines, combustion chambers and nozzles for jet propulsion, and like specialties are calling for super-alloys, for discussion of which space is lacking here. The alloys are in rapid state of development, and what is "standard" today becomes obsolete tomorrow. Evaluation of such alloys is made, for purposes of elimination and for load-carrying design values by high-temperature testing, according to the desired life, which may range from years to seconds. No one type of test puts the alloys in correct order for both long and short lives, and adequate design values are not obtainable short of service experience or simulated service tests that include the true conditions or service.

PRECIPITATION-HARDENED FERRITIC 17-7 STEEL. A relatively new material of construction, in which strength is of the order of that of cold-worked 18-8 austenitic stainless, is produced by precipitation hardening induced by titanium, in the presence of some aluminum. The corrosion resistance is similar to that of fully austenitic 18-8.

In the soft, annealed condition the properties approximate 120,000 psi tensile, 75,000 psi yield, with 3% (thin sheet) to 10% (bars over $^1/_2$ in.) elongation. Application of precipitation hardening heat treatment produces from about 210,000 psi tensile, 195,000 psi yield with the same elongation as in the annealed condition, down to about 150,000 psi tensile, 125,000 psi yield, with 5% (thin sheet) to 12% (bars over $^1/_2$ in.) elongation, according to the temperature (925 to 1050 F) and time for precipitation. These precipitation-hardened properties hold for large sections, no appreciable differences appearing between 1 in. diameter and 5 in. diameter bars. Castings as well as wrought shapes can be precipitation hardened.

On material of 170,000 psi tensile, a polished-bar endurance limit of 85,000 psi and a notched-bar one of 38,000 psi have been recorded. It is reported to hold its strength rather well up to about 600 F. Low-temperature behavior is like that of ferrite. The material can be welded and nearly full strength obtained if the joint is precipitation treated after welding. The range of properties obtained has been quite fully described (Ref. 41).

14. SUMMARY—GENERAL FERROUS MATERIALS OF CONSTRUCTION

The major commercially available ferrous materials of construction have been listed in the foregoing, with their ranges of room-temperature mechanical properties insofar as these are revealed by conventional tests and described in current purchase specifications. Seldom do such tests and specifications go to the root of the problem, suitability for intended processing and final use.

However, experience has shown the range of applicability of the different commercial materials, and the tests and specifications are designed to insure getting more material of like applicability. They do not imply that other materials may not be equally applicable, better, or cheaper; nor do they prove that all materials passing the tests and specifications are suitable. There are many minute details in the processing of irons and steels that affect serviceability. The effects of some of them can sometimes be differentiated by special tests that the user could apply, sometimes they are detectable only by actual or simulated service. Experienced producers, fully notified of the conditions under which the purchaser will process and finally use the material, will aid in the selection of proper and the avoidance of improper material. The more of a commercial material they have produced, the larger their background of experience as to its behavior. This fact, as well as the item of cost, is a reason for designing on the basis of commercial material that is in large production.

This is not invariably the case. Materials of well-known properties not now being produced in large volume may offer advantages not so obvious to the potential producer as to the consumer. It may require consumer pressure to make such material available. On the basis of British war experience, reported by Swinden (Ref. 42), leaded steels might come into this category.

The producers also know the replaceability of one material by another. If they are invited to suggest a replacement, rather than being hampered by imposition of strict chemical composition requirements as well as mechanical ones, they can often suggest a more available and more economical material, equally applicable, instead of the one the designer formerly used. When the designer specifies without consultation, the producer's duty is done when he meets the specifications. When he is consulted and fully informed on the way the material will be used, he tries to supply the material that is most suitable; and neither the conventional tests nor the current specifications may measure suitability. Previous comment on directional differences gives point to this statement.

Some of the idiosyncrasies of irons and steels that affect suitability, but for a discussion of which space is lacking here, are brought out in recent metallurgical publications (*ASM Metals Handbook*, 1948 edition, Cleveland, Ohio, and Bullens, *Steel and Its Heat Treatment*, fifth edition, in 3 volumes, John Wiley and Sons, 1948). Of the factors in design which, quite as much as the iron or steel selected, govern the serviceability of a part, castings are treated in the *AFA Cast Metals Handbook*. Those affecting life under repeated stress are treated in reference books (Refs. 43, 44).

15. SPECIAL-PURPOSE MATERIALS

Because they enter only highly specialized designs, some ferrous materials call for mere mention here, rather than description.

TOOL AND DIE STEELS. Tools and dies are of huge importance in fabrication, but, save for some wear-resistant parts, the steels used for them do not enter ordinary design. For information in this specialized field, the book by Gill and co-authors (Ref. 45) should be consulted.

The most important of this group is high-speed steel, originally high in tungsten. Prior to and during World War II, the alternative use of molybdenum and finally of compositions utilizing both, grew up. Many controversial discussions of the relative value of the various types have been published. The facts are summed up by Stotz (Ref. 46): ". . . during the height of the war production, no tools made of properly heat-treated molybdenum high-speed steel failed to hold their own with the equivalent steels in the tungsten family, and in many cases they did better." This is further evidence that chemical composition is of secondary and structure of primary importance, for the structures of the tungsten and molybdenum high speeds are indistinguishable.

SPECIAL CORROSION-RESISTANT FERROUS MATERIALS. For resistance to most acids, except to hydrofluoric and hot hydrochloric, a cast iron with about 15%

silicon is commercially available. It is weak, about 17,000 psi tensile, excessively brittle, and requires grinding instead of machining. Its use is an interesting case of protecting an installation against conditions where its brittleness would invite failure, in order to utilize an outstandingly good characteristic.

Austenitic cast irons, high in nickel or nickel and copper, are resistant to a variety of severe corrosive conditions and are machinable. Details are discussed in the *AFA Cast Metals Handbook.*

MAGNETS AND FERROUS MATERIALS USED FOR MAGNETIC PROPERTIES. For discussion of these special materials, see *ASM Metals Handbook and* Mechanical Properties of Metals and Alloys, *Circular* 447, National Bureau of Standards, 1943.

VALVE STEELS—INTAKE AND EXHAUST. For these, see Heron *et al.* (Ref. 47) and Hoyt (Ref. 48).

POROUS PRODUCTS. Porous shapes can be made by compressing iron or low-carbon steel powder in a die, sintering and shrinking the compact so made at elevated temperature, then repressing in a coining die, or machining to size when close dimensions are required. Large objects are difficult to produce with interior properties similar to the exterior because the powder does not effectively transmit pressure very far. Addition of carbon or graphite, with time for diffusion during sintering, as in carburizing, or carburizing by gaseous media, produces a steel-like matrix around the holes.

Because of the porosity, the powder iron objects rust easily and must be impregnated with oil. The product is used for very lightly loaded bearings where its oil retention is utilized. The strength is low, of the order of weak cast iron, and the brittleness is even greater. Attempts to produce objects quite free from porosity by use of extremely high pressures, to fill the pores with some other metal such as copper, and to improve properties by heat treatment of carburized objects have not been notably successful. Strength is inferior to that of solid cast iron or steel produced by conventional methods, and extreme brittleness is seldom avoided.

For production of small objects that are costly to machine from solid stock, in sufficient quantity to amortize the cost of presses, pressing dies, and coining dies, when the objects require only very mediocre strength and are protected against rusting and corroding, the process and products deserve consideration. However, they come more nearly at the bottom of the list of ferrous materials of construction than some overenthusiastic appraisals would indicate. Their best applications are where the porosity is utilized.

PROPERTIES OTHER THAN STRENGTH. Certain properties other than strength often enter into design. Ordinarily, however, they are not so crucial but that a knowledge of the general order of magnitude will suffice. When highly precise information must be had, specific tests of the exact material are needed.

POISSON'S RATIO. This approximates 0.3 for ferrous materials.

MODULUS OF ELASTICITY IN TENSION. The elastic modulus of steel is little affected by composition or structure. The usual design value is 29,000,000 psi. Values for ordinary steels ranging from 26,000,000 to 33,000,000 psi have been reported, but major deviations from 29,000,000 ± 1,000,000 are unlikely to be substantiated. The modulus increases with decrease in temperature and decreases practically linearly to about 25,000,000 or 26,000,000 psi at 700 F. Thereafter, it may in steels with high-temperature strength continue on the straight line to 1000 F or more, but ultimately drops rapidly.

Austenitic manganese and stainless steels, especially when strain hardened and not stress relieved, have slightly lower but about the same modulus over the lower part of the stress-strain diagram as other steels. However, the effective modulus up to the yield strength is lower because of the shape of the diagram. Values of 29,000,000 psi for quench-annealed and 27,000,000 psi for strain-hardened austenitic stainless are commonly used. Less decrease in modulus with increased temperature is to be expected than with ordinary steels.

Malleable irons show around 25,000,000 psi. The ordinary commercial gray cast irons range from about 12,000,000 psi for very soft, up to 23,000,000 for *very strong irons,* with 18,000,000 as a common value for average iron.

SPECIFIC GRAVITY. Specific gravity of carbon steel as rolled ranges from about 7.85 for low carbon to around 7.81 for over 1% carbon. Quenched to martensite it ranges from 7.83 to 7.76. Tempering at increasing temperatures raises the specific gravity to about the as-rolled figures. Cast steel is usually taken at about 7.85.

Ordinary constructional alloy steels run about the same as carbon steels, since the densities of most of the alloying elements do not differ sufficiently from that of iron for their small content to have much effect. Carbon and silicon are much less dense than iron, so that gray cast iron ranges from 7.0 for very soft iron to 7.3 for the stronger irons.

Malleable iron runs from 7.2 to 7.45, but the usual value taken is 7.30 to 7.40 with pearlitic malleable about the same.

The wrought austenitic stainless steels, low in carbon, run from around 7.93 for 18-8 to 7.83 for 25-12.

THERMAL EXPANSION. Thermal expansion values are ordinarily given in terms of the linear coefficient per degree centigrade times 10^{-6}. To transform to coefficient per degree Fahrenheit, multiply by 5/9.

The coefficient increases with increasing temperature, i.e., 11 to 12 from zero to 212 F, 13 to 15 from zero to 750 F for carbon and constructional alloy steels. Cast steels usually show 12 and 15. 18% chromium, 8% nickel stainless gives around $16\frac{1}{2}$ to 17 and 17 to 19 over these ranges. The 18-8 austenitic steel expands nearly half as much again as ordinary steels, the 25% chromium, 12% nickel about a quarter as much again. Plain chromium ferritic stainless steels expand less, about 90% as much, as ordinary steel.

Gray cast iron gives 10 to $8\frac{1}{2}$ and 12 to 13, malleable about 12 and 14, over these ranges. Detailed data are given by Mochel (Ref. 49). For cast materials, see the *AFA Cast Metals Handbook*.

THERMAL AND ELECTRICAL CONDUCTIVITY. In the ordinary ferrous materials conductivity decreases greatly with increase in carbon, in alloy content, and in temperature. Ordinary steels and cast irons have around one-eighth to one-ninth the thermal conductivity of copper at room temperature. In the quenched, martensitic condition, the conductivity is still low.

The austenitic steels have much lower conductivity, 18% chromium, 8% nickel, about one-twenty-fifth the thermal conductivity of copper at room temperature, and the Hadfield manganese steel of the same order. However, the conductivity of the austenitics rises slightly with temperature but is still low, less than half at 750 F of the value for ordinary steels and cast irons at 750 F.

Electrical resistivity in microhm-centimeters puts the ferrous materials in the following order as compared with copper, all the figures for ferrous alloys being approximate:

Copper	1.682
Low-carbon steel	11
Cast steel	15
High-carbon steel	20
Malleable	30– 35
Gray cast iron	50–100
Austenitic 18-8	90–130

Both the thermal and electrical conductivity figures reported by various observers differ greatly and cannot be depended upon for precise design.

CORROSION OF METALS

By Frank N. Speller

1. CORROSION IN GENERAL

Corrosion may be defined broadly as the deterioration or destruction of a metal by electrochemical or chemical action of its environment. Under most ordinary conditions of exposure the corrosion products comprise mainly oxides (more or less hydrated), carbonates, and sulfides. At high temperatures the products consist mainly of oxides, though indications are that corrosion of this type also progresses more rapidly when some moisture is present. Corrosion may be entirely superficial or may attack the intercrystalline boundaries and cause disintegration in the metal, as dezincification of brass or so-called caustic embrittlement in boiler steel.

In nearly all cases of corrosion at ordinary, or elevated, temperatures, comprising those most important in practice, the driving force of the corrosion reaction between metal and environment is electrochemical. This discussion refers mainly to iron and steel.

SOME ESTABLISHED FACTS REGARDING CORROSION. (*a*) In most cases both moisture and oxygen are necessary for corrosion. (*b*) The initial rate of corrosion usually is comparatively rapid, slowing as a protective film forms. (*c*) Surface films are important in controlling the rate and distribution of corrosion. (*d*) Increased rate of motion increases corrosion in water up to a certain velocity; the rate then may drop where strong protective films are formed. (*e*) Dissimilar metals in electrical contact accelerate corrosion of the ones that happen to be anodic. Galvanic action is a most active agent of corrosion. It occurs when two metals, one electronegative to the other, are placed in contact and exposed to moisture. (*f*) The composition of ordinary iron and steel has little or no effect on their relative rates of corrosion under water or under ground. Under these conditions the particular ferrous metal usually is not so important as environment. However, the chemical composition of wrought iron and carbon or low-alloy steel has considerable influence in corrosive atmospheres or acids. (*g*) Variation in the concentration or composition of a solution in contact with a metal tends to localize corrosion. Where this is due to oxygen in solution, the surface to which the oxygen diffuses most rapidly is cathodic to the area that is protected from diffusion of oxygen. The smaller the anodic areas in relation to cathodic areas the greater is the rate of penetration at anodic points. Corrosion, like other chemical reactions, increases with temperature, other factors being the same. Anaerobic bacteria in absence of oxygen may cause serious corrosion by breaking down sulfates in water or soil and indirectly accelerate corrosion by depolarizing cathodic areas as they remove the hydrogen.

The above, and other facts, are the basis of the electrochemical mechanism which now is generally accepted to explain corrosion in the presence of water (Refs. 1, 2, and 3).

2. MECHANISM OF CORROSION

CORROSION OF IRON OR STEEL IN GENERAL. While there is a vast difference in the amount of corrosion of iron and steel under different conditions, and while the relative corrosion varies with surrounding condition, certain fundamental causes underlie all corrosion.

Every metal when placed in water is subjected to a fixed tendency to go into solution. This is wholly a matter of electrochemical activity and varies to a definite extent with each metal. The initial reaction in the process of corrosion is analogous to solution in acid. The acidity of the water determines the initial speed of attack. As in all electrochemical reactions, however, the initial speed of solution soon slows down as the electrochemical couples which form over the surface of the metal become "polarized" due to the accumulation of hydrogen on their cathodic surfaces. Thus corrosion may be practically stopped. In the case of iron in aqueous media, ferrous hydrate film forms which also retards the rate of solution of the metal. In other words, iron, like all other metals, when in contact with water or a solution has a definite inherent tendency to go into solution in the form of electrically charged particles (iron ions). The solution must remain electrically neutral, and these positive ions can enter it only if an equivalent number of positive ions of some other elements are displaced. Thus, iron immersed in a solution of copper sulfate begins to go into solution, but, simultaneously, an equivalent amount of copper is plated out on the surface of the iron and protects it somewhat from further action. Similarly when iron is immersed in water, hydrogen is plated out and forms a thin invisible film on the iron surface.

This first stage of corrosion of iron, while essential, is not serious if the reaction between water and iron can be stopped at this point. In fact, it cannot proceed unless, in some manner, the hydrogen film protecting the metal is removed. This is usually accomplished by some depolarizing agent, generally free oxygen, which also combines with ferrous hydrate, forming insoluble ferric hydrate, commonly known as rust.

In solutions that are nearly neutral such as domestic water the amount of hydrogen evolved from cathodic surfaces in the gaseous form is small, equivalent only to about 3% of the overall corrosion. The amount of hydrogen released as gas increases with the acidity of the solution. The rate of corrosion is not materially influenced by the *p*H of the solution between *p*H 4 and 9. Low *p*H generally connotes increased hydrogen evolution while high *p*H (over 9) is usually accompanied by a lower rate of overall corrosion. At an intermediate *p*H (around 8) corrosion is localized, and the penetration rate may be serious.

This second stage of corrosion is thus caused by the oxidation of hydrogen and ferrous hydrate in solution by free oxygen from the atmosphere. Oxygen is soluble in water at normal temperature and pressure to the extent of about eight parts by weight per million, and as water readily dissolves oxygen, the reaction will continue until the metal has been destroyed, or the reaction may be stopped by exhaustion of the available supply of oxygen. The latter case is illustrated in any closed water system, such as a metallic water pipe, where the free oxygen will decrease as the water travels from the inlet. If, then, the pipe is long enough the corrosion will finally be reduced to a negligible amount.

FACTORS CONTROLLING CORROSION. Primary factors, which are those having to do with the initial tendency toward solution, are associated mainly with the metal itself. Secondary factors, those that influence the subsequent rate of corrosion, usually are much more important than primary factors. They depend mainly on the environment of the metal. The *main* factors influencing corrosion are listed below, regardless of their relative importance, which changes materially with environment.

Primary Factors Having to Do Mainly with the Metal. (1) Effective electrode potential of the metal in solution. (2) Chemical and physical homogeneity and texture of its surface. (3) Its inherent ability to form an insoluble protective film. (4) Overvoltage of hydrogen on the metal surface.

Factors Which Vary with Environment. (5) Hydrogen-ion activity (*p*H) in the solution. (6) Effective supply of oxygen in the solution adjacent to the metal. (7) Distribution of available oxygen on the metal surface. (8) Specific nature, concentration, and distribution of other ions in the solution. (9) Effective rate of flow of the liquid past the metal surface. (10) Presence of solid particles (dirt), or a coating of any kind, as mill scale, on the metal surface, or contact with other conducting material in the presence of an electrolyte. (11) Temperature. (12) Whether the metal is under static stress or cycles of alternating stress (the so-called corrosion fatigue). (13) The ability of environment to build up protective films on the metal. (14) Biological influences. (15) The corrosion reaction may be restrained or prevented by inhibitors, such as chromates, silicates, and carbonates in water.

While all the above factors are important under some conditions, the following deserve special attention and should be more clearly recognized. One or more factors usually dominate and therefore control the rate of attack in any specific environment; moisture in air and dissolved oxygen in water are common examples of "controlling factors."

Oxygen. In most cases, oxygen concentration and the rate at which oxygen diffuses to the metal are controlling factors when the metal is immersed in water or buried in soil. The part to which the oxygen diffuses most readily is cathodic to the adjacent areas that are shielded by protective coatings or other material. That is, the areas that are less accessible to oxygen corrode more rapidly than areas to which the oxygen has freer access. This and the galvanic effect from contact between dissimilar materials generally cause local corrosion or pitting.

Surface Films. Clean metallic surfaces exposed to air quickly acquire a film of gas or oxide, which at ordinary temperature is thin and invisible. At higher temperatures, the oxide is thick enough to give well-known characteristic colors, varying with the temperature. The nature and properties of the film depend on the composition of the metal itself and its environment. Aluminum and stainless steels, for instance, owe their high durability in certain environments to the formation of a continuous and permanent film that is stable under the conditions of exposure. In other environments the film may not form, or is quickly dissolved. The metal, therefore, has short life under such conditions. The addition of 0.25% copper to ordinary steel increases the life of the steel in industrial atmospheres, because of the formation of a dense adherent layer apparently consisting of iron oxide with a little copper oxide on the surface of the metal. When copper steel is immersed in water or buried in soil, this protective layer does not form. Under such conditions, copper steel is no more durable than ordinary steel without copper.

If the metal has no inherent power to form a protective film in solution, a film may be built up by adding film-forming reagents, as the chromates or alkalies, to the water. When removed from the solution, however, these films are only temporary. To secure permanent protection it is necessary to maintain in the water the proper concentration of chromate, or other material, used for this purpose. Films, when formed, should be self-healing, so that if injured or removed in any way a new film will form immediately. Chromium in iron over about 2% contributes to formation of a resistant invisible film under oxidizing conditions, but in dilute hydrochloric acid, where such films cannot exist, chrome steels dissolve even more rapidly than pure iron. Metals which acquire a stable protective film in a passivating environment become passive. In this condition they are at least temporarily resistant to corrosion when removed from the film-forming solution. The presence of thin invisible oxide films on passive material has been determined by the change in potential of the metal and by the removal of the films from the surface by selective dissolution of the underlying metal. (Refs. 4 and 5.) Where the corrosion products form spongy layers of irregular thickness, they do not protect, and may even accelerate, the normal action by interfering with the rate of diffusion of oxygen to the surface of the metal in water, and by holding moisture on the metal in the atmosphere.

Corrosion Fatigue. Metals subjected to repeated application of stress fail at considerably below their static ultimate tensile strength. However, the metal may be cyclically stressed indefinitely without apparent injury, below the so-called air fatigue or endurance limit. In absence of corrosion, carbon steels may have an endurance limit about one-half their tensile strength, but even a very small amount of corrosion present with cyclic stress will considerably reduce this endurance limit. Concentrated stress tends to accelerate the rate of corrosion. A notch is soon formed at the point of maximum stress, and, after this reaches a certain depth, the metal under cyclic stress fails by ordinary fatigue. The combined action of cyclic or repeated stress and corrosion is termed *corrosion fatigue*. The amount of cyclic stress that a metal will stand under these conditions depends mainly on its corrodibility and notch sensitivity and on the nature of the protective films formed by the metal or its environment. Hence, there is no fixed corrosion fatigue limit for any metal under all conditions of exposure. Corrosion factors predominate in corrosion fatigue and corrosion fatigue is usually independent of the tensile strength. Heat treatment of steel raises the tensile strength and the air endurance limit, but if it does not increase resistance to corrosion it will have no material influence on the resistance to corrosion fatigue. Even 18% chromium steel and 18-8% chromium-nickel steels show a considerable reduction in endurance limit in corrosive environment. Carbon steels in the as-rolled condition may fail at 20 to 75% of their air-endurance limit when kept continuously wet, depending on the composition of the water and the amount of oxygen present. (See also Ref. 3.)

An exceedingly small amount of corrosion is sufficient to depress the endurance limit of the metal under stress. In practice, therefore, it is important to prevent contact between stressed portions of metal and corrosive solutions. For instance, the endurance limit (based on 10^7 stress cycles at 1750 cycles per min) of SAE 1035 steel of 85,000 tensile strength showed:

In air	40,600 psi
In brine	24,600 psi
In brine containing H_2S	10,600 psi

Corrosion fatigue limits are higher in fresh water than in salt water—both aerated. They are not materially affected by changes in composition or heat treatment unless the steel is made thereby more resistant to corrosion. Chromium is the most effective alloying element for increasing the corrosion fatigue resistance in oil-well brines in absence of H_2S, but nickel is most effective when H_2S is present. A 3% Ni-Mo iron had a fatigue limit of 21,900 psi in the sulfide brine. Corrosion fatigue is manifested by cracks transverse to the direction of the maximum stress originating from corrosion pits. The most effective means for preventing corrosion fatigue is by reducing operating stress; the next most effective is by control of corrosion by corrosion-resistant alloys, protective coatings or inhibitors. Strong inhibitors like sodium chromate tend to prevent corrosion fatigue, except in high chloride waters.

An *inhibitor* is a chemical substance or mixture which, when added to an environment, usually in small concentration, effectively decreases corrosion. A *passivator* is a special form of inhibitor which forms a thin and relatively inert film of protective matter on the metal surface. This film is thought to consist of a very thin adsorbed monolayer of oxygen or passivating ions such as CrO_4, sometimes reinforced by a thin layer of reaction products. Metals thus passivated are less active and usually have a more noble potential than the active metal. (See also Refs. 6 and 7.)

3. CORROSION TESTS

CORROSION TESTING may be carried out in the laboratory or in the field under service conditions. Laboratory tests permit close control of dominant factors. Study of fundamentals, such as influence of oxygen concentration and velocity of motion and electrical potential differences, are examples. *Field tests* should be made with all variations in temperature, light, rate of motion, oxygen concentration, humidity, etc., that usually occur in nature. Laboratory tests are well adapted to the study of fundamentals and preliminary study of problems in the chemical industry, but tests of metals or protective measures are best made in the field or plant or, if time permits, in actual service. In no case should a factor such as an acid be introduced that does not occur in service. This has been done to accelerate the rate and shorten the time required but usually will give misleading results.

RELATIVE CORROSION. Difference of opinion regarding the relative corrosion of iron and steel and other metals apparently is due to failure to appreciate that different factors control in different environments. Factors external to the metal usually determine the corrosion rate, and these vary considerably with environment. The relative rate, therefore, may vary under different conditions of exposure. This fact should be the basic principle on which all corrosion tests (laboratory or service) are designed. Thus, in a study of metals, under atmospheric condition, the dominant factor should be an excess of oxygen. If the endurance limit of metal under water is in question, the test should be made in that environment alone. It is a mistake to take the results of tests made under one type of corrosion, i.e., in the atmosphere or in acids, and to apply the conclusions to the conditions in which entirely different factors control. An extreme instance is the well-known acid test made by exposing the metals to dilute sulfuric acid, in regard to which the ASTM has issued the following statement:

> The continued functioning during the past 25 years of the Committees on Corrosion of Iron and Steel of the A.S.T.M. has developed no further information as to the relation of the accelerated acid test to corrosion by the elements, or the trustworthiness of the acid test as a measure of natural corrosion.
>
> Studies were made to determine whether consistent results can be obtained in testing iron and steel sheets in 20% sulphuric acid, and if the results in acid compare favorably with the results of corrosion tests in the atmosphere. See Report on Total Immersion Tests, *Proc. A.S.T.M.*, Vol. 31, Part I, p. 176, 1931.
>
> A representative average set of samples from two sheets each of ten materials of iron and steel, both copper bearing and non-copper bearing, part of each sheet having been exposed to the atmosphere, was tested by five co-operating laboratories following an exact accelerated acid test procedure. The life in acid of similar sheets in atmospheric corrosion tests at Pittsburgh, Pa., and Key West, Fla., indicated that an acid test conducted by the procedure followed by the committee is not capable of consistent repetition. Further, the data from such an acid test should not be used to forecast the relative life of ordinary ferrous materials in the atmosphere.

Clearly, the subject of relative corrosion should be studied on the basis of type of service. The service test is the final criterion of the value of the metal, although judiciously made laboratory tests, with proper consideration given to the factors involved, will show under selected conditions a fair approximation of results in service. Three common types of service to be considered are atmospheric, water, and soil corrosion.

ATMOSPHERIC CORROSION. In atmospheric corrosion, oxygen is the dominant factor. In general, results of tests indicate little difference between the various kinds of iron and steel except where copper is present in excess of 0.07%. With copper content of 0.2 to 0.5%, the durability of steel in air is two to three times that of steel without copper in industrial or marine atmospheres. Figure 1 shows the influence of copper on corrosion. The greatest contrast between copper steel and noncopper steel is found in industrial atmospheres. Wrought iron without copper shows slightly longer life than noncopper steel under outdoor conditions. This probably is due to the better adherence of the products of corrosion to the rough surface of the metal. Sulfur in excess of 0.06% tends to increase the rate of corrosion in industrial air. For results of authoritative work on this type of corrosion, see reports of Committee A-5 in *Proc. ASTM* dating from 1915 to the present time.

A critical study of ASTM tests (see Ref. 8) is summarized as follows:

> A study of the Pittsburgh and Fort Sheridan results confirms previous conclusions as to the effect of copper. At the close of eleven years of observations of these tests, the sub-committee would direct attention to the fact that figures at the Fort Sheridan location confirm the findings at the Pittsburgh location, that copper-bearing metal shows marked superiority in rust-resisting properties as compared to non-copper bearing metal of substantially the same general composition under atmospheric exposure. (Report of Committee A-5 on Corrosion of Iron and Steel, *Proc. A.S.T.M.*, Vol. 28, Pt. I, p. 156, 1928.)

This paper also points out that at the Pittsburgh location, phosphorus combined with copper has beneficial effects from an atmospheric corrosion standpoint. Manganese and sulphur, within the limits of composition involved, seem to have little, if any, effect either way. The Fort Sheridan data, although limited on account of the incompleteness of the test, show similar beneficial results for high-copper material. The A.S.T.M. total immersion tests have been thoroughly studied, and, contrary to the atmospheric tests, the results indicate that the variation of the common elements, either singly or in combination, within range of composition and under the conditions of these tests, has no material influence on corrosion resistance and is entirely secondary to external conditions.

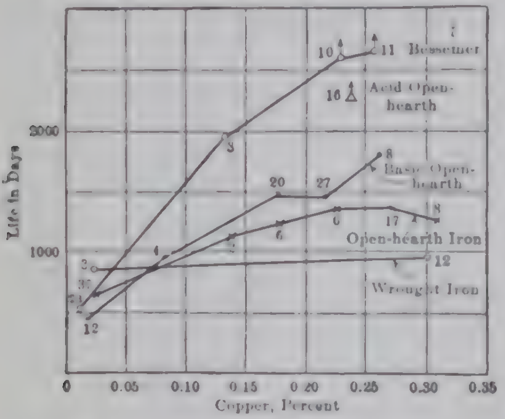

FIG. 1. Influence of copper on corrosion.

Tests of vent lines on the roofs of buildings were carried out by the National Tube Co., with wrought-iron, steel, and copper-steel pipe. Results based on the decrease in wall thickness indicated the relative loss of these metals to be as follows, taking steel as 100: wrought iron, 92%, copper steel, 36%.

Tests on hopper and gondola cars, constructed one-half of copper steel and the other half of plain steel, showed after 13 years that the copper steel had about 200% longer life in the hopper cars (subjected to some abrasion with corrosion) and 300% longer life for the side sheets of the gondolas (subject to corrosion only) in comparison with plain steel of the same composition. The number of cars tested was 100. J. S. Unger (Ref. 9) summarizes the experience with these cars as follows:

> (1) Paint adheres much better to copper-bearing steel in a car body than to plain open-hearth steel. (2) The saving in repainting cars, due to better adherence of paint to copper-bearing steel, would be sufficient to justify the use of copper-bearing steel in the bodies of steel freight cars. (3) Where mechanical abrasion has not been a serious factor, as in the side sheets of gondolas, the loss in thickness for the copper-bearing steel was only one-third as great as for the plain open-hearth steel. (4) Where the steel was subjected to severe mechanical abrasion as well as corrosion, the loss in thickness for the copper-bearing steel was approximately 60% as great as for the plain open-hearth steel. (5) From the results of this investigation, it can be conservatively stated that the use of all copper-bearing steel in the body of the cars would increase the life of the car body from 33 1/3 to 50%.

Service tests on copper steel tie plates, containing 0.25% copper, over a period of 11 years, show 5% loss in weight for copper steel and 20% loss for plain steel. Similar results have been obtained on cut spikes. (See Ref. 10.) Tests of 730 plain and a similar number of copper steel ties, in track for 9 years, indicate at least double the life for copper steel ties with a subgrade of broken slag and ashes for ballast. (See Ref. 11.)

Low-alloy steels containing small amounts of chromium, silicon, and sometimes up to 0.15% phosphorus last about twice as long as copper steels in industrial air. One of the best commercial low-alloy steels of this type has the following analysis: C 0.09, Mn 0.24, P 0.154, S 0.024, Si 0.8, Cu 0.43, Ni 0.05, Cr 1.07% (Cor-ten).

WATER CORROSION. When material is in continuous contact with water, the available oxygen is limited to its solubility in water. This affects the nature of the film formed by corrosion products, and therefore the rate of corrosion. Immersion tests were made by ASTM on the materials referred to above, in their atmospheric tests. The results show no material difference between the copper steels and similar steels without copper. Wrought-iron, steel, and ferrous alloys commonly used in the manufacture of pipe, tested in service in warm water and return steam pipe lines, show practically the same rate of corrosion and pitting as in Table 1. (See Ref. 1.)

Table 1. Summary of Grand Averages of Complete Record of Comparative Service Corrosion Tests of Pipe

Tests conducted in cooperation with outside interests by National Tube Co., Pittsburgh, Pa. Percentages based on steel = 100; and for galvanized materials, galvanized steel = 100.

Character of Service *	No. of Tests	Steel	Wrought Iron		Galvanized Steel		Galvanized Wrought Iron		Copper Steel		Scale-free Steel

* Character of service: HWS = Hot water; SR = Steam return; MW = Mine water; HSW = Hot salt water; RBA = Refrigerating brine and atmosphere.

Examination of test samples from various parts of the country indicates no fundamental difference in the rate of corrosion of any of these materials *in water*, except that the copper steels are somewhat more durable for return steam lines, where corrosion at times is of the wet and dry type as in air.

Low-alloy steels suffer about the same loss in weight as carbon steels or copper steels in industrial or sea water, but usually show about one-half the penetration by pitting. Steels having 2 1/2% chromium are exceptional in that they suffer only about one-half the penetration by pitting of other low-alloy steels or copper steel in water or air. This has been confirmed by the 10-year sea water test at Kure Beach, N. C. For further information and practical experience with steel pipe for water service, see Ref. 12.

SOIL CORROSION. Under ground, the dominant factor is local electrolytic action, resulting in pitting. The rate of penetration varies with moisture content, electrical resistivity, physical structure and chemical composition of the soil and ground water, and stray electric currents leaving the pipe (electrolysis).

The National Bureau of Standards, in co-operation with API, AGA, and a number of the leading pipe coating manufacturers, has conducted an extensive investigation of soil corrosion in forty-seven typical soils in the United States. This comprehensive test in-

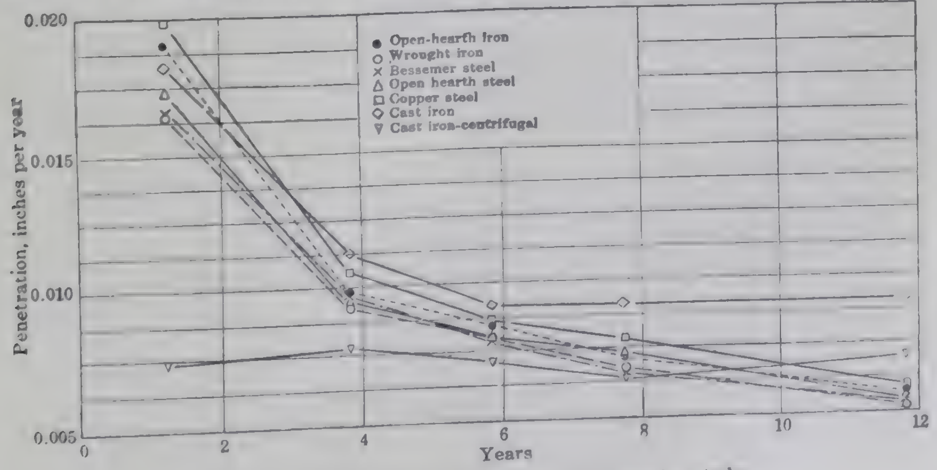

FIG. 2. Results of Bureau of Standards soil-corrosion study.

cluded some 15,000 samples. For detailed records of the tests, see Ref. 13. In Fig. 2 are summarized the weighted average results, based on maximum pits on ferrous metals from twenty-six corrosive soils included in these tests over a period of twelve years.

CHEMICAL CORROSION includes the action of acids and other chemicals. It is possible only to determine the relative durability of ferrous materials under such variable conditions by actual tests, in each case, in the laboratory or preferably in service. Before tests are made in the chemical industry the problem should be carefully appraised and all important factors determined and their relation to one another established.

4. PREVENTION OF CORROSION

Deterioration of metals can generally be prevented or reduced in three ways: (1) By using a more resistant metal. (2) By application of a suitable protective coating. (3) By making the environment less corrosive or (4) by cathodic protection (which might be included in the third group). The amount of protection specifically depends on the corrosive nature of the environment and must be chosen to suit the conditions and with a view to economy. In most cases involving iron or low-alloy steels the environment has much more influence on the rate of corrosion and pitting than the composition of the metal. This of course does not apply so generally to the more expensive types of corrosion-resisting ferrous or nonferrous metals.

5. PROTECTION AGAINST ATMOSPHERIC CORROSION

ORGANIC COATINGS.* Organic coatings are a class of materials, used mainly to protect metals from corrosion, which are applied as liquids and act chiefly as barriers between environment and the metals to be protected. Included in this class are varnishes, paints, lacquers, and enamels. Generally, their components are of two kinds, volatile and nonvolatile. The volatile component, called a thinner, consists of solvents and diluents. The nonvolatile component, i.e., the film-forming material, such as resin, oil, or wax, may also include both pigments and plasticizers.

The film-forming material is the barrier substance; but, since no organic film-forming materials completely exclude moisture from the metal surface, pigments may be added, either to reduce the rate of moisture penetration or to reduce the corrosiveness of the penetrating moisture. Also, pigments are added to reduce the harmful effects of sunlight upon the organic film, to give the vehicle more body so that it can be more readily applied, and to color the organic coating for decorative purposes. Some organic film-forming material may be too brittle initially or it may become too brittle during service. This property of a coated film can be controlled by means of plasticizers which increase the flexibility of the organic coating.

The proper application of an organic coating is one of the most important means of assuring the satisfactory performance of the coating film. The kind and quality of the ingredients of a coating are frequently blamed for the premature failure of an applied film, when the true cause may be improper preparation of the surface to be coated or the detrimental contamination of the surface prior to painting. For best results, the metal surface to be coated should be free of mill scale, corrosion products, oil, grease, and dirt before any coating is applied. The ultimate in surface cleanliness is not always attained because of economic factors; but when effective protection by organic films is the goal, this is too often false economy.

Pretreatments of metal surface are used extensively in shop coating to convert the metallic surface to a less active compound of the metal, such as metallic phosphate. If properly done, this results in cleaner surfaces and in better adhesion of the organic coating and reduces the spread of corrosion from holes in the organic coating.

The factors which cause corrosion should be understood before organic coatings for prevention of corrosion are applied. For example, if a metal is corroding at an accelerated rate because it is coupled with a more noble metal, coating the potentially corrodible surface incompletely results in more intense attack at discontinuities and in deep pitting or, in some cases, perforation of the metal. In such cases, both the coupled metals should be coated.

An organic coating is essentially a barrier. However, unless great care is exercised in application and in maintenance, discontinuities are sure to be present either initially or during the service life of the coating.

---

* By G. W. Seagren, senior fellow, Mellon Institute.

Definitions. The following definitions are recommended by the American Society for Testing Materials (ASTM D-16-47):

Varnish: A liquid composition which is converted to a transparent or translucent solid film after application as a thin layer.

Bituminous Varnish: A dark-colored varnish containing bituminous ingredients, either oil- or spirit-type varnish.

Oil Varnish: A varnish which contains resin and drying oil as the basic film-forming ingredients and is converted to a solid film by chemical reaction.

Spirit Varnish: A varnish which is converted to a solid film primarily by solvent evaporation.

Paint: A pigmented liquid composition which is converted to an opaque solid film after application as a thin layer.

Oil Paint: A paint that contains drying oil or oil varnish as the basic vehicle ingredient.

Water Paint: A paint that contains a water emulsion or dispersion as the vehicle.

Enamel: A paint which is characterized by an ability to form an especially smooth film.

Lacquer: A liquid coating composition containing, as the basic film-forming ingredients, cellulose esters or ethers and plasticizers, with or without resin.

Protective Coatings for Metals, by R. M. Burns and A. E. Schuh, Reinhold Publishing Corporation, New York, 1939. (*ACS Monograph Series*, No. 79.)

PROTECTION OF PIPES. Both cast-iron and steel water mains corrode more or less and lose carrying capacity rapidly by tuberculation unless protected from corrosive waters. Interior protection is now usually obtained by the hot application of bituminous enamel about $^1/_{16}$ in. thick by the centrifugal process usually under AWWA Standard Specifications 7A.5 and 7A.6–1940.

Air-drying paints have been materially improved for service in water, but except perhaps as a priming coat for bituminous enamel they lack the desired durability for protection of water lines. Certain baking-type phenolic-resin formulations are, however, much more desirable than air-drying paints and promise to prolong considerably the life of steel pipe and tanks in hot- and cold-water and steam-heating systems.

Paints for underwater service at normal temperatures have been greatly improved during recent years by the use of phenolic-chlorinated rubber and other synthetic resin bases. Substitution of tung oil for all or 60% of the linseed oil previously used and the addition of inhibitive pigments have also played an important part in prolonging the useful life of paints in water (Ref. 14). Several of these paints are now being made by leading manufacturers.

Portland cement coatings have given long service as interior coatings for large water mains and can be readily applied to old tuberculated mains after cleaning (Ref. 1, pp. 347–355). The exterior of water mains are usually protected from soil corrosion by reinforced bituminous coatings with cathodic protection.

Preparation of Metal Surface for Painting. Sand or steel grit blasting and acid pickling are now recognized as the best methods of preparing the metal for painting. All mill scale and rust should be completely removed and the paint applied when the surface is dry and at a temperature above 10 C (50 F). Mill scale is cathodic to iron and therefore promotes pitting.

Aqueous inhibitive solutions containing phosphoric acid applied to the clean metal before painting have been found to reduce but not entirely prevent blistering of paints *in water*, but their effect is markedly different with different paints. These inhibitors are usually most effective with the better-class paints. Under *atmospheric* exposure the beneficial influence of these inhibitive washes is much less noticeable or entirely lacking (Ref. 15).

CEMENT. Ironwork often is bedded in concrete which, if free from cracks and voids, is an efficient protection. The metal should be cleaned and then preferably washed with neat cement before embedding. Rich Portland cement mixtures are used for lining of steel and cast-iron water pipe.

BOWER-BARFF PROCESS. Dr. Barff's method was to heat articles to be coated to about 1800 F and inject steam heated to 1000 F into the muffle. George W. Maynard and A. S. Bower used air instead of steam, then carbon monoxide (producer gas) to reduce the red oxide. (See also Ref. 16.)

RUSSIA AND PLANISHED IRON. Russia iron is made by cementation and slight oxidation. W. Dewees Wood (U. S. Patent 252,166 of 1882) treated planished sheets with hydrocarbon vapors or gas and superheated steam within an airtight and heated chamber.

NITER PROCESS is an old process improved by Col. A. R. Buffington in 1884. The articles are stirred about in a half-and-half mixture of fused sodium and potassium nitrate (saltpeter) to which is added manganese dioxide in the ratio of 1 part oxide to 50 parts niter by volume. They then are suspended in the vapors, dipped and washed in boiling water, and finally immersed in hot oil or wax for protection against corrosion. Pure chemicals are essential. This process is used for small arms and pieces which cannot stand the high heat of other processes. The temperature of the bath should be 600 to 650 F to yield a temper blue, and 100 F to yield the dark gun-metal finish used for rifle parts.

PHOSPHATE COATINGS (Ref. 17). Iron and steel articles, properly cleaned and immersed in a dilute phosphoric acid solution saturated with one or more of the metals iron, manganese, or zinc, become coated at the point of solution with crystalline phosphate. The reaction of the acid with the metal takes place with the evolution of hydrogen gas until the metallic surface is converted to a protective phosphate coating. The protective value of such coatings depends upon their continuity and for this reason thickness and density of coating are important factors. Coatings having a wide range of thickness can be produced depending upon the method of cleaning prior to phosphating, solution concentration, and time of processing. Because no electric current is used and formation of the coating is solely dependent upon the phosphating solution contacting the metal surface, uniform coatings are produced on irregularly shaped articles, in recessed areas, and on threaded surfaces with facility equal to that on flat surfaces.

Coslett Process. The first commercial application of phosphate coatings followed the proposal of Coslett in 1907 to treat iron and steel articles in a hot dilute phosphoric acid solution with a control agent such as iron filings. Iron and steel articles immersed in this solution for 3 to 4 hours at boiling temperature become coated with a rust-resisting ferrous phosphate coating. The difficulty in obtaining uniform coatings, the great amount of suspended matter adhering to the work after rinsing, and the nonuniform appearance made the adoption of the process slow.

Parkerizing. Parkerizing utilizes a phosphating bath so prepared and replenished that the solution remains in balance at all times and is easy to operate and control. In operation the properly cleaned articles are immersed in the hot Parkerizing bath for 15 to 45 minutes where a thin layer of the metal being treated is dissolved, resulting in the formation of the Parkerized coating chemically bonded to the base metal. Immediately following the Parkerizing treatment, processed articles are rinsed in clean hot water and dried. The affinity of Parkerized coatings for oil, wax, or color is utilized in practice to enhance further their corrosion resistance. Frequently such coated articles are finished by dipping in nondrying or drying type of oils, followed by centrifuging to remove the excess. The finish has a black matte appearance.

Bonderizing. Bonderizing produces on iron, steel, zinc, cadmium, and aluminum surfaces a corrosion-inhibiting phosphate coating for increasing the adhesion and resultant durability of paint finishes. Since its introduction in 1929 it has become recognized as a useful method of preparing surfaces for painting wherever the maximum durability of the paint finish is required. Usually either the article is immersed in the phosphating solution or the solution is sprayed onto the articles to be coated. In general, small parts which can be more conveniently handled as a unit load are treated by immersion application whereas larger parts such as refrigerator cabinets, automobile bodies, and fenders are treated by spray application. The immersion process requires 2 to 5 min for application of the coating, and the spray process 45 sec to 1 min.

GALVANIZING is a method of coating steel or iron articles with zinc, the product being known as galvanized steel or iron. Galvanized coatings usually resist, for a reasonable time, such ordinary corrosive conditions as fairly pure air, moderately hard domestic waters, sea water, and brines. The zinc, particularly under atmospheric conditions, often becomes covered with a protective layer or film believed to be a zinc-hydroxide-carbonate mixture. Zinc is anodic to iron and therefore protects the base metal, where exposed, until the adjacent outer layer of zinc is dissolved. Galvanized coatings are unsuitable where the corroding agent is very acid, as in certain mine waters and industrial solutions, or where the solutions are excessively alkaline, e.g., calcium brines with an excess of caustic alkalinity. Favorable water pH values are between 6 and 8.5 and temperatures below 130 F. In brines the pH should not exceed 8. Very hot soft water (over 160 F) often attacks galvanizing rapidly. The potential of zinc to iron above 140 C is reversed in some water so that the pitting rate is increased.

Galvanized coatings are commercially applied: (*a*) by dipping the article in molten zinc; (*b*) by electroplating; (*c*) by heating in contact with zinc powder.

Hot-dip Galvanizing. Articles to be hot-dipped-galvanized usually are cleaned by acid pickling, washed, and fluxed by immersion in a bath of zinc ammonium chloride or hydrochloric acid. They then are dipped in molten zinc maintained at 830 to 920 F. When the steel has reached approximately the zinc temperature, requiring a few seconds in the case of wire and several minutes for heavier sections, it is drawn slowly from the bath, allowing time for draining. In the case of wire, excess zinc often is removed and the coating smoothed mechanically by asbestos or charcoal wipers. Long, slightly corrugated rolls are similarly used for sheets. The article may cool in air, producing a spangled (crystalline) zinc surface, or it may cool rapidly in water, producing a matte surface.

Adherence of zinc coatings depends on the formation of suitable zinc-iron alloys. Some grades of wire and sheets, conduit pipe, etc., requiring maximum bending qualities are made with light coatings consisting largely of zinc-iron alloy formed by wiping after dipping. Where bending requirements are secondary and maximum corrosion resistance is desired, as for other grades of iron and sheets, galvanized water pipe, galvanized wire, etc., the galvanizing should be considerably heavier, and with more pure zinc in the coating. The average weight of coating applied varies from 1/2 to 2 1/2 oz per sq ft of covered surface, depending on the thickness of base metal, temperature, and time in bath, and amount of wiping. The protective value varies directly as the thickness of the zinc.

In the process of galvanizing, tin is at times added to the zinc bath to improve the spangle, whereas aluminum may be added to improve the fluidity of the bath and brightness and smoothness of the coating. The vapor of burning sulfur or ammonium chloride dust on the zinc surface as it comes from the bath has been used to improve brightness, but the sulfur may impair the corrosion resistance of the zinc.

Electrogalvanizing. Electrogalvanized zinc coatings are applied to conduit pipe, wire, and intricate shapes. Electrogalvanized coatings on the threads of pipe couplings prevent sticking or galling of the threaded joints, and generally are used for tubular goods in petroleum production. Articles to be electrogalvanized may be cleaned by pickling with or without the aid of electric current, or machined surfaces may be cleaned with alkaline grease removers. The zinc is deposited from sulfate or cyanide baths, using low-voltage plating current (see ASTM Specification A164-40 T, Electrodeposited Zinc on Steel).

GALVANIZING BY CEMENTATION. SHERARDIZING. Sherard Cowper-Cowles (England) refined and perfected the process of cementation with zinc, and British and United States patents were granted to him in 1902 for the method known as sherardizing. It consists in packing the articles to be sherardized, usually steel, in a retort with zinc powder known as *blue dust*. The retort or drum is tightly sealed, and by suitable means so heated that its contents attain a temperature approaching the melting point of zinc. The melting point of zinc is 786 F, and sherardizing usually is carried on at 600 to 700 F, although it can be done at temperatures above or below this range. Better results are obtained if the drums are slowly rotated, and this generally is done in order to bring a fresh supply of dust into intimate contact with the articles being treated. The time required is 2 to 4 hours. After drums are removed from the heating oven, they are allowed to cool before being opened. Prolonged heating and slow cooling of steel articles embedded in zinc dust, which is a poor conductor of heat, tends to soften them, which is highly desirable for objects which must be cut and bent.

Blue dust is a natural by-product of smelting zinc, but, when especially made of greater purity and uniformity for the purpose of sherardizing, is known as sherardizing zinc dust. It consists of minute particles of zinc metal, each encased in a thin skin, shell, or pellicle of zinc oxide. Commercial sherardizing zinc contains about 95 to 97% metallic zinc. The remainder is chiefly zinc oxide, with traces of impurities such as iron and lead. The resultant coating is a true zinc-iron alloy, ranging from $FeZn_3$ at the base metal line to $FeZn_{10}$ near the surface, and a layer of relatively pure zinc on the exterior; exact analysis naturally is difficult.

Characteristics of a sherardized coating are *color*, a rich gray; *texture*, which is matte, caused by innumerable minute fissures not visible to the unaided eye, and has a velvety feel; *ability to receive and retain paints*, varnishes, enamels, etc., due to the bonding effect in the minute fissures; *uniform distribution and penetration*, making possible the effective coating of irregularly shaped and hollow articles, screw threads, holes, etc., without building up on corners or actually filling up depressions, although allowance must be made for thickness on threads and other closely fitted parts; *ductility and tenacity*, a reasonable amount for bending, as in electric conduit; *ability to take a high polish*, the surface being relatively hard.

Corrosion Resistance of Sherardizing. Concerning exposure to ordinary attacks indoors, and when exposed to weather and the zinc is oxidized, Rawdon says (Ref. 18):

> The coating gradually assumes a dark appearance as the iron likewise is oxidized, finally becoming a very dark gray and almost black if the iron content is not too high. Coatings high in iron, and hence containing the iron-rich compound, usually show a red dusty surface on weathering from the ferric

oxide produced. A wrong impression often is formed concerning such coatings, that is, that the coating has been entirely corroded away and that the red dust indicates an exposure of the base metal. It can generally be shown that such is not the case.

When this color is not due to rusting of the base metal, the red or yellowish formation usually disappears in a short time, and the surface darkens. The black coating is believed to be the magnetic oxide of iron. When sherardizing acquires this surface formation it becomes highly resistant to atmospheric corrosion. The relation of coating thickness to durability is important, since a heavy coating is, for mechanical reasons, objectionable on some articles, particularly those subject to bending and flexing. For Comparative Life of Different Types of Zinc Finishes, see Ref. 19, p. 95.

TESTS AND SPECIFICATIONS FOR GALVANIZED COATINGS. Galvanized coatings usually are specified as a given weight of zinc per unit area. If bending or forming is anticipated, bend tests may be specified. Coatings may be expressed as ounces of zinc per square foot of surface, and determined by weighing a suitable sample of the galvanized article, removing the zinc, and reweighing. The usual means of removing the zinc is with hydrochloric acid containing sufficient antimony chloride to prevent attack on the base metal. The minimum thickness of galvanized coatings, particularly on wire, also is expressed in terms of the Preece test, which consists of dipping the zinc-coated article in a neutral solution of copper sulfate (sp. gr. 1.186 at 18 C) for periods of one minute, washing and wiping between each dip until the zinc is penetrated, as shown by the formation of adherent copper on the exposed surface of the steel. Coating weight is expressed as number of dips to cause failure. For details of both methods, see Standard Methods of Determining Weight of Coating on Zinc Coated Articles, ASTM Specification, Designation A90-39 and A239-41. (See ASTM book of standards.)

Specifications for most commercial products covering weight of coating and bend tests when required are available in 1946 and subsequent ASTM Standards, Part 1A, Metals.

On sheets, coating weights are given as weight per square foot of sheet, i.e., 2 sq ft of coated surface. Ordinary coatings on sheets range from 1.25 to 2.75 oz per sq ft of sheet coated on both sides. The weight of zinc per single covered surface would be one-half this amount. Zinc coatings on pipe, structural shapes, etc., generally range between 1.5 and 3.0 oz per sq ft of covered surface. The weight of coating on wire varies with the size of wire and process of coating and, except in fine sizes, will range from 0.15 to 1.25 oz per sq ft of covered surface.

LEAD COATINGS. Lead is very resistant to certain types of corrosion, and lead coatings on steel have been used to some extent, where sulfate and other insoluble lead compounds are formed. A thin coating of lead, however, is difficult to apply, either by electroplating or hot dipping, so as to be sufficiently free from pinholes to be effective when submerged in corrosive water. The atmospheric resistance of such coatings usually is quite good. Hot-dipped lead-tin alloy sheets, known as terne plate, are extensively used. Wrought steel or iron pipes protected on the interior by thick lead tubes mechanically applied, when carefully installed with suitable fittings and valves, are effective for carrying corrosive acids and similar liquids.

FLAME SPRAYING (metallizing) is the process by which zinc, aluminum, and other metals in the form of wire or powder are passed through an oxyacetylene flame by air pressure and thus atomized and plated on the material to be coated. Steel should be well cleaned by grit blasting. Plastics that can be powdered can be applied by this process. Sprayed zinc coatings have a porous outer surface and afford a good base for an outer coat of paint. Sprayed zinc, 0.010 in. thick, has protected steel dams in fresh water for 10 years.

CADMIUM COATINGS (electroplated) have a pleasing appearance and afford satisfactory protection, indoors, against rusting. Cadmium like zinc is usually anodic to iron and therefore protects by sacrifice of the coating. It has the advantage of not developing bulky and unsightly corrosion products, in contrast to zinc. However, the increasing cost of cadmium and its inferiority to zinc in marine and industrial atmospheres have limited its field of use. Practically all cadmium coatings are electroplated from cyanide baths.

A joint atmospheric corrosion test on electroplated coatings being conducted by the American Electroplater's Society, the ASTM, and the National Bureau of Standards includes cadmium coatings. After 180 weeks in several types of atmospheres, all the quality ratings of the cadmium coating are lower than for zinc of similar thickness (Ref. 19, p. 127). The cadmium coatings are somewhat closer to zinc in marine locations. The salt spray test indicated cadmium coatings superior to zinc, but this has not been borne out in subsequent field tests in marine air.

RUST-RESISTING METALS. Iron. Various modifications of plain iron and steel have been introduced to give better service under atmospheric conditions. These grades of iron and steel are included in the ASTM corrosion tests referred to on p. 3-06.

Copper steel has found a wide commercial application on account of its slow rusting properties under industrial and marine atmospheric conditions of exposure. (See Ref. 20.) Addition of 0.15 to 0.25% copper at an increased price of about $3.00 per ton usually will prolong the life of the metal two times under such conditions. (See also p. 3-06.)

Corrosion-resistant alloys, containing high percentages of chromium and nickel, are widely used in industrial and marine atmospheres.

6. PROTECTION AGAINST UNDERWATER CORROSION

The main factors controlling rate of corrosion in water are dissolved oxygen and carbonic acid, temperature, rate of motion, and soluble salts in the water. The chemical composition of ferrous metals, within rather wide limits, does not seem to have a marked influence on the character or the amount of corrosion. The high-chromium series of steels are an exception to this. With cold water the rate of corrosion is usually slow, but in hot water the corrosive action is accelerated according to the temperature, the rate being about doubled for every 25 F increase in temperature.

Localized corrosion or pitting usually is much deeper near mill scale, especially where the scale is thick and firmly adherent, due to the cathodic character of the scale with respect to iron. Old rust acts somewhat similarly but is less harmful. Removal of mill scale and rust reduces the tendency to pitting, provided the metal itself is fairly homogeneous and free from strain. Surface finish is a greater controlling factor in corrosion of iron and steel than the variations in the composition of the metal itself.

Within certain limits, corrosion varies directly with the temperature and the rate of flow and also with the composition of the water. Corrosion is likely to be more rapid on unprotected metal with increasing velocity of the water. The amount of corrosion is almost directly proportional to the amount of oxygen in the solution in the water. Hot-water heating systems show practically no corrosion after 50 years of use, whereas hot-water supply systems, operating at the same temperatures, have failed in 6 to 8 years. The only difference between the two is that in the heating system free oxygen is excluded, while the water in the supply system usually is saturated with that gas.

DEACTIVATION AND DEAERATION OF WATER. In some cases it is more economical to prevent internal corrosion by removing dissolved oxygen from the water, especially with hot water. Oxygen removal may be accomplished: (1) by mechanical deaeration for which there are two or three satisfactory designs of apparatus in use; (2) by the chemical combination of the oxygen with some material such as scrap and sheet iron or sodium sulfite. The two methods may be combined by using mechanical deaeration to remove most of the oxygen and chemical treatment for the remainder.

Dissolved oxygen is usually the controlling factor in corrosion of iron in water. In the return condensate lines of heating systems, free CO_2 is also of prime importance. These facts have been established by laboratory experiments and by experience in service. Means for removal of free oxygen and CO_2 from water have been considerably improved in recent years. (See Speller's chapter in Ref. 2; also Ref. 27.)

CHEMICAL TREATMENT OF WATER. Hot-water Heating Systems. The water is usually obtained from domestic supplies and is either soft or of medium hard quality. These systems are closed except for a small air vent so that the free oxygen is soon exhausted, and corrosion is therefore negligible. A small amount of corrosion occurs in water which has been deactivated in this way, with the evolution of hydrogen which may be drawn off through petcocks near the tops of radiators. By adding sufficient caustic soda to bring the *p*H of the water up to 8 or 8.5, the generation of hydrogen can be prevented and the gas nuisance eliminated.

Cooling water that is recirculated in contact with the atmosphere, as in spray ponds or secondary heat exchangers (as for stationary diesel or gas engines), can generally be inhibited to prevent serious corrosion of steel by the addition of about 500 ppm of sodium chromate, which may be reduced materially after the protective film has formed. Aeration does not impair the efficiency of chromates. The optimum amount required, which depends on the composition of the water, may be determined approximately by laboratory tests. In closed cooling systems (recirculating) it is better to keep the concentration above 1000 ppm, or even higher, where much chloride is present (Ref. 21). The manufacturers who specialize in the production of chromate for such service are usually able to give useful information as to the amount required for specific service (Ref. 22).

Sodium nitrite gives about the same protection as the chromate. Water-soluble organic inhibitors (such as the glucosates or tannin compounds) may also be used as inhibitors in cooling systems. (While these are usually somewhat more expensive than the chromates, they have no toxic effect in the concentrations employed.) Advice on their application and concentrations required for specific conditions may be obtained from manufacturers. (See also Ref. 22.)

Domestic Water Systems. Natural waters are selected and often treated for domestic use. They are used for boiler feed and cooling, with or without local treatment.

Water treatment for very large systems is usually limited by the cost to *p*H control and deposition of $CaCO_3$ scale. The carbonate balance system of treatment aims at having an excess of $CaCO_3$ present so that a continuous protective layer of carbonate or lime is deposited on the inside of pipe and containers. This is accomplished by adjusting the *p*H with respect to the carbonate, bicarbonate, and free CO_2.

Silicate of soda has been used since 1920 to protect iron, lead, and brass water pipe. For most water a solution of $Na_2O : 3\ SiO_2$ is recommended and may be fed by any convenient type of proportional feed apparatus.

Hexametaphosphate and other polyphosphates of soda have proved to be highly useful in preventing the formation of scale deposits due to excess of calcium and magnesium salts in water; 2 to 5 ppm is usually sufficient for this purpose. These compounds also prevent discoloration from iron when added in the proportion of 2 to 1 ppm of iron in the water. For this purpose the phosphate must be added before the water is chlorinated or exposed to air.

When the water at normal temperature is in turbulent flow (about one foot per second or higher in pipe under one inch in diameter) 10 ppm hexametaphosphate has been shown to retard corrosion in hot soft waters, apparently by formation of an insoluble film on the metal (Ref. 23).

Pipe Materials for Water Supply. The choice lies mainly between galvanized ferrous pipe, copper, and two or three grades of brass. Each is available in three thicknesses and standard inside nominal diameters with threads and couplings. Copper is available in thinner wall pipe provided with solderable streamline copper fittings.

Soft waters (nearly neutral) are much more reactive with metals than those of higher primary alkalinity or when supersaturated with calcium carbonate. Under the latter, galvanized pipe in cold-water lines has given satisfactory results.

For monumental buildings, copper or 85(Cu) 15(Zn) brass of the standard pipe gage is advisable unless the water is deactivated by removal of the dissolved oxygen or by other adequate treatment.

Brasses with 60 to 67% copper are dezincified in some corrosive waters, and in certain localities they are not much more serviceable than galvanized iron or steel pipe. The zinc may be leached out locally, leaving a plug of porous copper, or the dezincing effect may be spread out, resulting in a general weakening of the pipe, which is especially noticeable under the threads. Dezincification is retarded by the use of silicate of soda (8 ppm added silicate). Brasses with 85% or more copper do not show this (Ref. 24). Evidently no kind of pipe, ferrous or nonferrous, should be used indiscriminately without regard to the corrosive character of the water.

Promising synthetic resin coatings of the baking type have been developed that are proving useful for protection of hot-water tanks and piping.

In salt or fresh water there is no material difference in rate of pitting of wrought iron, steel, low metalloid steels, or copper-bearing steels. This is contrary to relative performance of these metals in atmosphere. Low-alloy steels containing nickel and chromium are not enough better in this respect to warrant their extra cost in form of pipe for water-supply services in general.

ANAEROBIC BACTERIA cause serious damage from corrosion of cast iron and steel pipe in certain soils or water. They thrive when sulfates and a little organic matter occur, provided the soil or water is low in free oxygen. These bacteria take up hydrogen and reduce sulfates with liberation of free sulfur or hydrogen sulfide. When they operate on the metal surface they evidently obtain most of their hydrogen from cathodic surfaces and thus keep the corrosion process active as in ordinary corrosion by the familiar electrochemical process of depolarization. Anaerobic bacteria may operate in water, as in the water seals of gas holders, within a *p*H of 5.5 to 8.5. Protection may be obtained by reinforced coal tar coatings $^1/_{16}$ in. or more thick and by cathodic protection, or by keeping the *p*H of the water over 9. (See Ref. 2.)

CORROSION IN STEAM BOILERS. Internal corrosion may be caused by the use of water containing free acid, by water containing chloride of magnesium, which decomposes when heated, liberating acid, or by water containing air or carbonic acid in solution. External corrosion rarely takes place when a boiler is kept hot, but when cold it is likely to corrode rapidly in those portions where it joins the brickwork or where it is covered by dust or ashes, or wherever water may lodge (Ref. 2, p. 520).

STEAM CONDENSATE lines suffer from corrosion due to free oxygen and carbon dioxide in the condensate. Oxygen is a more important factor than CO_2, but the combination is worse than either separately. The noncondensable gases entrained with the steam accumulate so that the amount present in the vapor phase may be much higher than in the incoming steam. As a result, the amount dissolved in the condensate may equal, or even exceed for short periods, the amount entrained by the steam (see Ref. 25). There are four means available to minimize corrosion in steam condensate systems: (1) Treatment of boiler feed water to eliminate free O_2 and CO_2 in particular. (2) Design to minimize re-solution of deleterious gases in the condensate. (3) Chemical treatment of the condensate, as by addition of an amine of suitable composition. (These are volatile alkalies like ammonia.) (4) Use of more resistant metals. Highly resistant alloys like 18-8 steel, for economic reasons, can be used only on limited sections. (See also Refs. 1 and 26.)

CORROSION OF NONFERROUS PIPES. The corrosion of brass, zinc, and other metals is greatly retarded or entirely stopped by removing oxygen from the water in contact with these metals. Brass and copper piping are sometimes seriously attacked by heated water under pressure. Water heated in a domestic copper boiler of the usual type may lose nearly one-half of its free oxygen in passing through the heater. Brass pipes after 10 or 12 years frequently have lost most of the zinc content by "dezincification" (Ref. 2, p. 69) in some waters. The same has been observed in brass condenser tubes. It is now generally recognized that no one metal will meet all requirements of service. Ordinary brass pipe (35 Zn, 65 Cu) is adequate where the water is fairly pure and low in chlorides; red brass (15 Zn, 85 Cu) is much more durable where the water carries considerable amounts of soluble salts. It is much less likely to suffer dezincification. This grade is preferable for sea water. Copper pipe usually is more durable than brass for practically all domestic water service. (See Refs. 24 and 28.)

7. PROTECTION AGAINST SOIL CORROSION

SOIL CORROSION is usually highly localized and is caused by electrochemical action resulting from variations in the soil and solutions therein. Low-alloy steels, i.e., steels with less than 10% chromium, do not show enough advantage, from an economic standpoint, under severe soil corrosion to warrant their use, and the solution of the problem of longer life of underground pipe is practically limited to a selection of suitable protective coatings and electrical protection (p. 3-16).

Soil corrosion varies considerably from point to point on pipe lines. On long lines serious damage is confined to 10% or less of the line as a rule. It is, therefore, advantageous to have a soil survey of the territory through which the pipe line will run, before deciding on the type of protective coating, if any, to be used. Much progress has been made in the study of soil factors at the National Bureau of Standards, so that a careful survey, judiciously interpreted, with regard to all the factors involved, should give an approximate idea of the corrosivity of the soil. (See National Bureau of Standards Research Papers 95, 298, 329, 359, 365, and Bulletin C450.) A soil survey, with experience on pipe lines situated in similar soils, affords a fairly sound basis for selecting the most economical coating, with or without cathodic protection, for a particular location.

BITUMINOUS COATINGS have been used mostly for underground protection. They consist of the well-known coal tar and asphalt dip coatings, preferably applied, after removing all grease, dirt, and loose mill scale, by vertically dipping the pipe in a bituminous bath at about 350 F. The melting point of the asphalt mixture should be varied between 140 and 190 F to suit climatic conditions. Coatings of this type, properly applied at the mill, are suitable only for mild corrosive conditions, but afford fair protection on the inside of water mains. In wet, marshy places, or in alkaline or acid soils, more substantial protection often is required. A thicker coating may be applied at the trench, but the pipe should receive either an asphalt or coal tar dip coating, or a coating of a suitable bituminous primer applied cold at the plant before shipment to prevent rusting in transit. Bituminous coatings usually are reinforced with saturated asbestos felt wound spirally on the pipe over the dip coat. A Fiberglas fabric is now available for this purpose. In certain soils, unless these bituminous coatings have a high melting point and are unusually rigid, they are subject to soil stress; that is, some soils have a tendency to cling to the coating and pull it away from the pipe when the soil shrinks by drying, or irregular pressure in the trench may distort the bitumen and cause thin spots in the coating. In such soils a shielding material should be used to prevent damage to the coating by soil stress. Experience shows that many bituminous coatings that otherwise would have afforded adequate protection have been destroyed or rendered ineffective in this way. Thin, stiff, rolled steel sheet (26 gage) or copper foil may be used as a shield. Asphalt mastics consisting of 30% bitumen and 70% of a graded sand have been used with good results, especially for protection of pipe conveying hot oil through very corrosive soils. These mixtures are applied about $\frac{3}{8}$ in. thick, on 8-in. pipe, and, while expensive, this coating has proved superior to other bituminous coatings.

PORTLAND CEMENT CONCRETE has been used for over 40 years for protecting pipe in highly corrosive soil. It has a record as one of the most practical means of affording permanent protection. The minimum thickness usually is about 1 in.; the mixture may be applied in a wooden box surrounding the pipe. A portable steel form has been developed so that a concrete mixture consisting of 3 sand and 1 Portland cement can be poured around the pipe with a minimum thickness of [illegible]/8 in. Portions of the Hetch Hetchy steel conduits have been protected with such a mixture applied $\frac{1}{2}$ in. thick, wrapped with fabric.

Portland cement coatings are applied in such thicknesses at about the same cost as fabric-wrapped bituminous coatings on 8-in. to 12-in. pipe lines. Concrete coatings offer some resistance to stray electric currents but should not be relied upon to protect pipe against electrolysis. Where pipe lines pass under electric railways, or in situations where complete electrical insulation is necessary, the line has been effectively protected by boxing and coating with hot asphalt with a minimum thickness of about 1 in. for a distance of 100 ft on each side of the track.

A comprehensive field test of pipe coatings has been conducted under the auspices of the National Bureau of Standards with the cooperation of committees of the American Gas Association and API. These tests were made on short lengths of pipe, and also on operating oil lines, and give useful information concerning the durability of all materials now available for such protection. (See Refs. 13 and 29.)

CATHODIC PROTECTION. Cathodic protection is obtained by rendering the structure that is corroding slightly cathodic to the surrounding water or soil by means of a controlled difference of potential. This method, which has proved satisfactory and economical on a number of gas and oil pipe lines underground, has also been applied successfully to the protection of the inside of water-storage tanks and other structures that are in contact continuously with water. Protective coatings that insulate a large portion of the metal surface will very materially reduce the total amount of protective current that it is necessary to impress on bare anodic areas to arrest corrosion. This treatment is usually too costly to use without a fairly good coating. The protective current may be obtained from zinc, aluminum, or magnesium anodes or it may be supplied from external sources and applied through large anodes of steel or iron scrap, surrounded underground with coke breeze.

For each structure it is necessary to determine or estimate the minimum current density required, and to place the anodes so that the necessary protection of all parts in the corrosive area can be obtained most economically. In water having relatively high electrical conductivity, such as sea water, this is easy as compared with fresh-water systems. In the latter the composition of the water is a major factor. It is therefore desirable to obtain experienced engineering advice in the analysis of these problems in order to obtain an accurate estimate of the minimum current density required. The protective current is controlled by the potential between the anode and the structure to be protected. Usually at least 0.25 volt difference in potential between the buried structure and soil is required to insure sufficient current density on the structure as cathode to prevent corrosion.

Rectifiers have generally proved to be the most practical means for supplying the necessary current for protection of surfaces in contact with neutral waters (Ref. 30). Zinc, magnesium and aluminum anodes (in suitable back-fill) have given good protection in medium- and low-resistance soils, as for river crossings on pipe lines. (See Ref. 2.)

8. SOURCES OF INFORMATION

The economic importance of corrosion control, now generally recognized, is evidenced by the numerous committees of national engineering societies working on various phases of the problem. The ASTM has conducted extensive field tests and has formulated specifications.

The National Association of Corrosion Engineers, organized in 1944, is the center of discussions on corrosion prevention (headquarters, Southern Standard Building, Houston 1, Texas). The NACE publishes a monthly journal that contains a bibliography of current literature. Another bibliography, dealing particularly with the metallurgical side of the problem, is published monthly in *Metal Review* by the American Society for Metals, and *Chemical Abstracts* (American Chemical Society) covers papers of interest to the chemical engineer.

The Electrochemical Society has a corrosion division that specializes on the fundamental phases of the subject, but includes in its published transactions many papers on applied aspects. A *Corrosion Handbook*, including about 100 articles by specialists covering scientific data and its engineering application, has been prepared and sponsored by the Society (Ref. 2).

The National Bureau of Standards has carried on authoritative research and tests on soil corrosion, as has the American Petroleum Institute and the American Gas Association in their respective fields.

CORROSION RESISTANCE OF METALS AND ALLOYS

By H. H. Uhlig

9. FORMS OF CORROSION

Metals corrode by uniform surface reaction as in the rusting of iron or tarnishing of copper, but in addition they may exhibit attack in other forms. These forms are particularly important in some of the corrosion-resistant alloys for which uniform corrosion is often negligible, but corrosion along localized paths may be correspondingly pronounced. In the application of these alloys, therefore, proper regard should be paid to factors of alloy treatment and environment that are known to influence localized attack.

Precautions are included in the following discussion pointing out some of these factors. For example, with some alloys proper quench from high temperatures and, in others, stress relief anneal are necessary conditions for satisfactory corrosion resistance in even mild environments.

The various types of corrosion can be summarized as follows.

UNIFORM CORROSION. This is corrosion represented by rusting of iron, tarnishing of silver, fogging of nickel, or high-temperature oxidation of iron or stainless steels.

PITTING. This is localized attack at random on specific areas, in the form of either shallow, saucer-like indentations or deep, narrow channels appearing at times as if a worm had bored through the structure.

DEZINCIFICATION AND PARTING. Dezincification is a type of corrosion occurring with zinc alloys in which there is preferential loss of zinc. Yellow brass, for example, often corrodes in water or aqueous solutions in this fashion. A porous, mechanically weak, spongy copper remains, having approximately the same shape as the original brass. If dezincification occurs only in relatively small areas, it is known as *plug-type* dezincification. If the attack is general, it is called *layer-type* dezincification.

Parting is similar to dezincification in that one component of the alloy is preferentially corroded. It is known primarily in the noble metal alloys. An alloy of 25% silver and 75% gold, for example, corrodes preferentially in nitric acid, leaving as residue a porous mass of pure gold.

INTERGRANULAR CORROSION occurs locally along narrow regions of metal separating the various metal crystals or grains one from the other. This type of attack occurs, for example, when Duralumin (aluminum plus approximately 4% copper) or 18-8 stainless steel (18% Cr, 8% Ni, bal. Fe) is improperly heat treated and later exposed to a corrosive environment. Heat treatment in specific temperature zones, either intentional or accidental, precipitates compounds in the grain boundary regions, making the boundary a preferred path for electrochemical action. Mechanical failure of an appreciable cross section of metal can be rapid when this type of corrosion is the cause.

CRACKING. Corrosion in the form of cracking has either one of two names. If a metal exposed to a corrosive environment contains residual stresses, or is constantly stressed externally, the failure is called *stress-corrosion cracking*. If the metal is repeatedly or alternately stressed, such as in vibration, the failure is called *corrosion fatigue*.

Stress-corrosion Cracking. Practically speaking, any of the commercial metals or alloys are subject to stress-corrosion cracking if the conditions of combined stress and environment are critical. Unless the corrosive environment is of the right kind and concentration, however, no cracking occurs. For this reason, stress corrosion cracking is not commonly observed in practice. If the environment happens to be the critical one, however, trouble is encountered whenever the metal is subject simultaneously to the critical stress. For example, stressed brasses crack in ammonia or amine plus oxygen atmospheres, but not in other atmospheres; stressed stainless steels (18-8) crack specifically in slightly acid chloride solutions, some stressed aluminum or magnesium alloys fail similarly in neutral chlorides; and steel stressed beyond the elastic limit cracks in hot concentrated nitrates or caustic soda.

Corrosion fatigue, on the other hand, is an accelerated form of fatigue cracking owing to the presence of a corrosive environment. The environment is not so specific as with stress-corrosion cracking. The metal, furthermore, subject to the same alternate stresses, may or may not fail in the absence of such an environment, depending on whether the stresses are above or below the endurance limit (the endurance limit is the maximum stress that may be applied to a metal without failure after an indefinitely large number of stress cycles). In general, the endurance limit is reduced, and in some cases may not exist at all (reduced to zero stress) if the metal is corroded at the same time that it is subject to alternate stresses. Air alone is sufficiently corrosive to some metals alternately stressed, e.g., copper and brass, so that their endurance limits are reduced as much as 15 to 25% below corresponding values in vacuum. A similar effect is found also for steel, but the reduction is not so large.

EMF AND GALVANIC SERIES. Dissimilar metals coupled together and exposed to an electrolyte form a short-circuited galvanic cell, the operation of which usually accelerates corrosion of one metal in the couple. This accelerated corrosion is called galvanic corrosion. The extent of galvanic corrosion depends on conductivity of the electrolyte, polarization characteristics of the electrodes, and operating potential of the cell. In general, the EMF series (Table 1) has been used to indicate the approximate potential difference one may expect when two metals are coupled together. Metals near one another in the series show relatively less potential difference than metals far apart. For this reason, the statement is made that it is inadvisable to couple together metals far apart in the series, since the increased potential difference induces larger currents, causing correspondingly greater galvanic corrosion.

There are limitations to the use of the EMF series, however, that deserve consideration. The EMF series essentially arranges metals in order of their standard reversible potentials, that is, metal potentials in solutions of their respective ions having thermodynamic concentration (activity) equal to one molal. In practice, however, concentrations of this

$Au = Au^+ + e^-$	1.68
Noble Metals	

kind are seldom, if ever, met with so that actual potentials in more dilute solutions may actually reverse the potential relations predicted by the EMF series. For example, metal complex ions sometimes form which reduce the thermodynamic activity of metal ions to very small values and thereby increase tendency of the metal to corrode. Complex formation of this kind accounts for the fact that copper, although normally noble to iron, is less noble than iron in cyanide plating baths, and, for the same reason, lead, although normally cathodic to iron or steel, reverses potential relations in alkaline waters.

Another limitation of the series arises because of the phenomenon of passivity. As practically employed, many metals such as aluminum, chromium, and nickel are passive, that is, they behave electrochemically as more noble metals. Since the EMF series deals only with metals in their nonpassive or active state, no information is given relating to

Passive or Cathodic Metals

the passive metals as employed in practice. Furthermore, the EMF series as defined is unable to accommodate the many alloys of commerce.

To take care of these factors adequately, the so-called galvanic series have been proposed. These series arrange metals, and also alloys, in order of their actual potentials in some stated environment. The potentials are not necessarily thermodynamically reversible, as are the potentials in the EMF series, but may represent steady-state potentials and, correspondingly, the actual potentials that operate when dissimilar metals are coupled in the given environment. Table 2 lists the galvanic series for sea water. In general, coupling metals far apart in this series leads to more serious galvanic corrosion than coupling metals adjoining one another. The series may be similar or may vary as one chooses environments other than sea water.

10. THE STAINLESS STEELS

DEFINITION. Iron-base alloys containing 12% chromium or more are known as stainless steels. They are so called because of their property of passivity at and above this critical percentage of chromium. Passivity is related to thin films, possibly monolayers of adsorbed substance (gases, solute ions, etc.) on the surface, and a specific electronic structure of the alloy which combine to impart considerable corrosion resistance. Sometimes a thicker corrosion-product layer, forming later, supplements the corrosion resistance accounted for by the primary film.

At elevated temperatures, the stainless steels are oxidation resistant, attributed again to their chromium content. The chromium content, however, is not critical as in passivity, the oxidation resistance increasing with percentage of chromium. The mechanism of resistance at high temperatures lies in physical protection of relatively thick layers of metal oxides on the surface.

Table 3. Stainless Steels

(All AISI Types)

Martensitic

Type 403: 0.15 max C, 11.5–13.0 Cr. **Thermal treatment**: Full annealing, cool slowly from 1500–1650 F; low annealing, cool slowly from 1200–1400 F, hardening, cool rapidly from 1700–1850 F; tempering, 400–1400 F.

Used for steam turbine blades.

Type 410: 0.15 max C, 11.50–13.50 Cr. **Thermal treatment**: Same as type 403 *(above)*.

Type 414: 0.15 max C, 11.50–13.00 Cr, 1.25–2.50 Ni. **Thermal treatment**: Full annealing, not practical; low annealing, 1200–1300 F, hardening, cool rapidly from 1800–1900 F; tempering, 400–1300 F.

Somewhat better corrosion resistance than type 410.

Type 416: 0.15 max C, 12.00–14.00 Cr, 0.60 Mo or Zr, 0.07 min P, S, or Se. **Thermal treatment**: Full annealing, cool slowly from 1500–1650 F; low annealing, 1200–1400 F; hardening, cool rapidly from 1700–1850 F; tempering, 400–1400 F.

Free machining and nonseizing. Suitable for automatic screw machine.

Type 420: C >0.15, 12.00–14.00 Cr. **Thermal treatment**: Annealing, cool slowly from 1550–1650 F; low annealing, 1350–1450 F; hardening, cool rapidly from 1800–1900 F; tempering, 300–700 F.

Can be hardened to 500 Brinell. Maximum corrosion resistance only in fully hardened condition.

Used for cutlery, valves, surgical instruments.

Type 431: 0.20 max C, 15.00–17.00 Cr, 1.25–2.50 Ni. **Thermal treatment**: Full annealing, impractical; low annealing, 1150–1225 F; hardening, cool rapidly from 1800–1950 F; tempering, 400–1200 F.

Called 16-2 stainless steel. Better corrosion resistance than types 410, 420, 430, and 440.

Type 440A: 0.60–0.75 C, 16.00–18.00 Cr, 0.75 max Mo. **Thermal treatment**: Full annealing, cool slowly from 1550–1650 F; low annealing, 1350–1450 F; hardening, cool rapidly from 1850–1950 F; tempering, 300–800 F.

Greater hardness than type 420. Greater toughness than types 440B and C. Types 440A, B, C are used for cutlery, valves, instruments.

Type 440B: 0.75–0.95 C, 16.00–18.00 Cr, 0.75 max Mo. **Thermal treatment**: Full annealing, cool slowly from 1550–1650 F; low annealing, 1350–1450 F; hardening, cool rapidly from 1850–1950 F; tempering, 300–800 F.

Corrosion resistant only in fully hardened condition. Greater hardness than type 440A and greater toughness than type 440C.

Type 440C: 0.95–1.20 C, 16.00–18.00 Cr, 0.75 max Mo. **Thermal treatment**: Full annealing, cool slowly from 1550–1650 F; low annealing, 1350–1450 F; hardening, cool rapidly from 1850–1950 F; tempering, 300–800 F.

Acquires highest hardness of a corrosion-resistant steel. Corrosion resistant only in fully hardened condition.

Table 3. Stainless Steels—*Continued*

(All AISI Types)

FERRITIC

Type 405: 0.08 max C, 11.50–13.50 Cr, 0.10–0.30 Al. **Thermal treatment**: Low annealing, 1350–1500 F; hardening, not appreciably hardenable.

Can be cooled from elevated temperatures without marked hardening.

Type 406: 0.15 max C, 12.00–14.00 Cr, 3.50–4.50 Al. **Thermal treatment**: Low annealing, 1350–1500 F; hardening, not appreciably hardenable.

Used for electrical resistor elements. Low thermal coefficient of electrical resistance up to 1000 F.

Type 430: 0.12 max C, 14.00–18.00 Cr. **Thermal treatment**: Low annealing, 1400–1500 F; hardening, not appreciably hardenable.

Better corrosion resistance than type 410. Used for automobile trim, nitric acid equipment, etc.

Type 430F: 0.12 max C, 14.00–18.00 Cr, 0.60 max Mo or Zr, 0.07 min P, S, or Se. **Thermal treatment**: Low annealing, 1250–1400 F; hardening, not appreciably hardenable.

Free-machining variation of type 430. Suitable for automatic screw machines.

Type 442: 0.25 max C, 18.00–23.00 Cr. **Thermal treatment**: Low annealing, 1400–1500 F; hardening, not hardenable by thermal treatment.

Slightly better corrosion and heat resistance than type 430. Resists destructive scaling up to 1600 F.

Type 443: 0.20 max C, 18.00–23.00 Cr, 0.90–1.25 Cu. **Thermal treatment**: Low annealing, 1400–1500 F; hardening, not hardenable by thermal treatment.

Added corrosion resistance to some types of chemicals because of Cu content.

Type 446: 0.35 max C, 23.00–27.00 Cr, 0.25 max N. **Thermal treatment**: Low annealing, 1450–1600 F; hardening, not hardenable by thermal treatment.

Contains maximum chromium consistent with commercial malleability. Used principally for high-temperature oxidation resistance. Resists destructive scaling up to 2000 F. Embrittles (only at room temperature) on prolonged heat treatment at 750–1025 F.

AUSTENITIC

Type 301: 0.08–0.15 C, 16.00–18.00 Cr, 6.00–8.00 Ni. **Thermal treatment**: Annealing, cool rapidly from 1850–2050 F; hardening, hardenable by cold work only; stress relieving, 400–750 F.

Attains high tensile strength and ductility by cold working. Used largely as cold-rolled sheet, strip, and wire.

Type 302: 0.08–0.15 C, 17.00–19.00 Cr, 8.00–10.00 Ni. **Thermal treatment**: Same as type 301 (*above*).

This is the general-purpose austenitic stainless steel. Corrosion resistance better than type 301. Used largely in annealed condition. Can be cold worked to high tensile strength, but with slightly lower ductility than type 301.

Type 302B: 0.08–0.15 C, 17.00–19.00 Cr, 8.00–10.00 Ni, 2.00–3.00 Si. **Thermal treatment**: Same as type 301 (*above*).

Resistance to scaling better than type 302. Used for high-temperature applications.

Type 303: 0.15 max C, 17.00–19.00 Cr, 8.00–10.00 Ni, 0.60 max Mo or Zr, 0.07 min P, S, or Se. **Thermal treatment**: Same as type 301 (*above*).

Free machining and nonseizing 18-8. Suitable for automatic screw machines.

Type 304: 0.08 max C, 18.00—20.00 Cr, 8.00–11.00 Ni. **Thermal treatment**: Same as type 301 (*above*).

Low carbon 18-8; somewhat better corrosion resistance than type 302. It is less readily sensitized with respect to intergranular corrosion in welding.

Type 308: 0.08 max C, 19.00–21.00 Cr, 10.00–12.00 Ni. **Thermal treatment**: Same as type 301 (*above*).

Somewhat better corrosion and heat resistance than type 304.

Type 309: 0.20 max C, 22.00–24.00 Cr, 12.00–15.00 Ni. **Thermal treatment**: Annealing, cool rapidly from 1900–2050 F; hardening, hardenable by cold work only; stress relieving, 400–750 F.

Good heat-resistant qualities.

Type 310: 0.25 max C, 24.00–26.00 Cr, 19.00–22.00 Ni. **Thermal treatment**: Annealing, cool rapidly from 1900–2100 F; hardening, hardenable by cold work only; stress relieving, 400–750 F.

Still better heat-resistant qualities than type 309.

Type 316: 0.10 max C, 16.00–18.00 Cr, 10.00–14.00 Ni, 1.75–2.75 Mo. **Thermal treatment**: Annealing, cool rapidly from 1850–2050 F; hardening, hardenable by cold work only, stress relieving, 400–750 F.

Superior corrosion resistance, especially to chlorides, nonoxidizing acids, and the atmosphere. Superior creep strength at elevated temperatures. Susceptible to intergranular corrosion if heated in range 800–1650 F, but less so than types 302 or 304.

Type 321: 0.10 max C, 17.00–19.00 Cr, 8.00–11.00 Ni, Ti 5 × carbon, min. **Thermal treatment**: Annealing, cool rapidly from 1750–1950 F; hardening, hardenable by cold work only; stress relieving: 400–750 F.

"Stabilized" 18-8. Recommended for parts fabricated by welding which cannot be annealed subsequently. (For spot welding, types 304 and 316 are also satisfactory without subsequent annealing.) Also recommended for parts to be used between 800 and 1650 F.

Type 347: 0.10 max C, 17.00–19.00 Cr, 9.00–12.00 Ni, Cb 10 × carbon, min. **Thermal treatment**: Annealing, cool rapidly from 1850–2050 F, hardening, hardenable by cold work only, stress relieving, 400–750 F.

"Stabilized" 18-8. Recommended for parts fabricated by welding which cannot be annealed subsequently. (For spot welding, types 304 and 316 are also satisfactory without subsequent annealing.) Also recommended for parts to be used between 800 and 1650 F.

TYPES. There are three classifications of the stainless steels. Their compositions, thermal treatment, and miscellaneous characteristics are listed in Table 3.

Martensitic stainless steels are magnetic, and can be hardened by heat treatment.

Ferritic stainless steels are magnetic, and are not appreciably hardenable. Above approximately 20% chromium they embrittle if heated for long periods in the temperature range of 750 to 1025 F. This embrittlement, however, is observed only at room temperature, the alloys having normal ductility at operating temperature.

Austenitic stainless steels are nonmagnetic and are not hardenable by heat treatment. They are annealed by rapid cooling from high temperatures, acquiring maximum softness and ductility. They can be hardened considerably by cold work. In this process, some compositions become not only hard and acquire high strength, but magnetic as well. Types 308 and 309, because of their higher nickel content, become less magnetic than some other types, whereas type 310 remains essentially nonmagnetic on cold working. The cold-worked materials are also corrosion resistant.

The austenitic alloys corrode *intergranularly* if heated for appreciable lengths of time within the range of 800 to 1650 F, or are slowly cooled in this range. The minimum time for sensitization to intergranular attack amounts to a few minutes in the higher temperature range, and many hours in the lower range of temperature. In welding operations, sensitization usually occurs to some extent at areas away from the weld. The higher the carbon content, the more readily are the alloys sensitized. Alloys so sensitized must be quenched from 1850 to 2050 F to restore corrosion resistance.

The "stabilized" steels (types 321 and 347) are immune to this type of attack, regardless of heat treatment or welding operation. The type 316 alloy (Mo 18-8), although attacked less rapidly than type 302 or 304, will also corrode intergranularly if heated in the temperature range cited above.

Recently, special low-carbon grades of stainless steels have been produced which are less susceptible to intergranular corrosion when heated in the critical temperature zone than are the usual unstabilized types.

GENERAL CORROSION CHARACTERISTICS. Stainless steels, in general, have maximum corrosion resistance when quenched from high temperatures. Cold work tends to decrease only slightly their resistance to some media; tempering decreases resistance somewhat more.

They possess maximum passivity and, hence, maximum corrosion resistance in fully aerated or oxidizing solutions. For example, they show outstanding corrosion resistance to *nitric acid*. They are not satisfactorily resistant to *sulfuric acid* except in aerated dilute concentrations, or in acid properly inhibited with Cu^{++}, Fe^{+++}, or NO_3^- additions. The type 316 alloy is satisfactorily resistant to *sulfurous acid*. None of the stainless steels withstands *hydrochloric acid*.

All the alloys resist attack by *alkalies* at ordinary temperatures, but corrode at elevated temperatures, particularly in caustic alkalies that are of medium or high concentration. The alloys can be used with *ammonia* or ammonium hydroxide at room temperature without attack. They are nitrided in contact with ammonia at elevated temperatures. Stainless steels hardened by nitriding or carburizing suffer in some degree loss of passivity and corrosion resistance.

The halogen ions break down passivity, and stainless steels, therefore, tend to corrode in such solutions. In hydrochloric acid or in nonoxidizing acid halide salts, e.g., $AlCl_3$, corrosion is uniform. However, in neutral or near-neutral halide salts, corrosion usually occurs by pitting. In *sea water*, for example, serious pitting may be observed after a few months. Type 316 (Mo 18-8) is more resistant, but pitting of this alloy in sea water eventually occurs (usually within 2 1/2 years or less). All the alloys pit badly in heavy metal chloride solutions, such as ferric chloride, cupric chloride, and mercuric chloride. Buried underground, their corrosion resistance is good. They tend to fail by pitting in some types of *soil*, but this tendency is much less pronounced than in sea water.

The stainless steels, particularly those of high alloy content, remain bright for many years in rural *atmospheres*. A slight tarnish may form in industrial or marine atmospheres. Usually, attack can be avoided or minimized by frequent cleaning of the surface so as to remove grime and dust. Type 316 18-8 is the most resistant of the common types of stainless steels.

Stainless-steel surfaces in any application should always be kept clean and bright. At a contacting surface in presence of moisture, it is common for an electrolytic cell to establish itself so that a pit forms underneath the area of contact (contact or crevice corrosion). If the surface is clean, however, such cells do not set up and the surface remains bright. For maximum corrosion resistance, therefore, crevices, cracks, or overlapping joints should be avoided, particularly if such areas permit the accumulation of dirt or act as reservoirs for stagnant solutions.

PITTING. Since the stainless steels, properly heat treated, corrode, if at all, usually by pitting, the following precautions help avoid attack of this kind:

1. Avoid concentration of halogen ions.
2. Insure uniform concentrations of dissolved oxygen or oxidizing solutions. Solutions should be agitated, and stagnant pools avoided.
3. Increase *p*H. Appreciably alkaline chloride solutions cause less pitting or none at all compared to neutral or acid chlorides.
4. Operate at lowest temperatures possible.
5. Apply cathodic protection. Stainless steels, galvanically coupled to steel, aluminum, or zinc, for example, apparently do not pit in sea water.
6. Cleanse or burnish surfaces periodically, thus helping to avoid contact (crevice) corrosion. Alkaline cleaners and stainless steel wool are satisfactory.

STRESS-CORROSION CRACKING. Stainless steels are subject to stress-corrosion cracking in specific media, particularly acid chlorides or dilute hydrochloric acid. The failure is usually transgranular, distinguishing stress-corrosion cracking of these alloys from intergranular corrosion, discussed above, not requiring stress. Failure from this source does not depend on precipitated carbides; hence the columbium and titanium stabilized stainless steels are also susceptible. Because conditions for cracking require both a minimum stress and a highly specific environment, failures of this kind are only rarely observed in service.

Boiling 42% magnesium chloride is extremely active in producing stress-corrosion cracking of the stainless alloys and, hence, is used in accelerated tests. In laboratory tests, cracking has been observed with boiling calcium chloride, cobalt chloride, zinc chloride, lithium chloride, and ammonium chloride solutions. Ethyl chloride containing water can also cause cracking.

The stress necessary to cause transgranular cracking in specific media can be residual or applied. Stencil-stamped specimens and deep-drawn stainless steel sheets will crack in some of the media listed above. Stresses resulting from cold straightening, quenching, grinding, or differential thermal expansion are adequate to cause stress-corrosion cracking. The minimum critical stress for stress-corrosion cracking of 18-8 in boiling 42% magnesium chloride has been found to be less than 20,000 psi.

The ferritic stainless steels are less susceptible than the austenitic alloys. With the austenitic alloys, it is reported that resistance to cracking increases with nickel content. Furthermore, maximum sensitivity of 18-8 to cracking in a hot calcium chloride solution containing $^{1}/_{10}$ to 1% mercuric chloride increases with carbon content up to 0.045%, then decreases. For similar alloys containing higher nickel, the corresponding carbon content for greatest sensitivity is said to be higher.

GALVANIC COUPLING. The stainless steels when passive have approximately the same galvanic potential as silver. Hence, they are cathodic to and somewhat accelerate corrosion of, e.g., steels, zinc, and cadmium with which they may be coupled. When they lose passivity, as in dilute acid chlorides, they have approximately the same potential as iron. Since they are applied usually as passive materials, it is commonly satisfactory to couple one type of stainless steel with another type, or with metals such as silver, copper, aluminum and aluminum alloys, nickel, Inconel, and Monel.

REMOVING OXIDES FROM THE SURFACE. A stainless-steel surface oxidized by heat treatment or welding operations can be cleaned either by sand blasting, grinding, or pickling. Sand blasting is particularly useful for general removal of scale when a heavy layer is formed. It is not recommended if surfaces are to be polished.

Pickling is accomplished using the following solution:

Sulfuric acid (specific gravity 1.84), 10 parts by volume.
Water, 100 parts by volume.
Rock salt, $^{1}/_{4}$ lb per gal of solution.
Temperature, 160 to 180 F.
Time, 10 to 45 min.

This solution is used only to loosen the scale. It can be made more active by addition of hydrochloric acid. Attack of the metal is reduced by addition of a corrosion inhibitor. The work after pickling should be rinsed in hot water and scrubbed.

If further treatment is required, the following solution should be used. This solution is also useful alone for removing light oxide or tarnish films not requiring the pretreatment above.

Nitric acid (specific gravity 1.42), 10 to 20 parts by volume.
Hydrofluoric acid, 1 to 4 parts by volume.
Water, 100 parts by volume.
Temperature, 130 to 150 F.

The latter should be used only under conditions of adequate ventilation since the fumes are toxic. The work, as before, should be rinsed and scrubbed thoroughly in hot water.

Sometimes the stainless steels are "passivated" after fabrication and heat treatment to impart maximum corrosion resistance. This operation, however, is not necessary after the pickling treatments outlined above, since no permanent additional corrosion resistance is imparted. The process is carried out in this solution:

Nitric acid (specific gravity 1.42), 5 to 20% by volume.
Temperature, 130 to 140 F.
Time, 10 to 20 min.

The work finally should be scrubbed and rinsed in hot water.

MATERIALS FOR PICKLING TANKS. Tanks for any of the pickling or "passivating" solutions are most conveniently constructed of wood. Although they will not give long life, they are easily constructed and inexpensively replaced.

Wooden tanks lasting somewhat longer than more ordinary tanks are constructed with an outer box of cypress coated with bakelite base varnish. This box is lined with a bituminous paint, then with fir also coated with bakelite finish.

Acidproof brick can also be used. Such tanks consist of an outer shell of steel or concrete lined with heavy asphaltum. Acidproof brick is "set in" and bonded with acidproof cement.

Tanks for the nitric acid "passivation" bath can be made from welded type 304 low-carbon 18-8.

11. SILICON-IRON ALLOYS

Silicon-iron alloys containing 14–15% silicon are known under various trade names, some of which are Duriron, Tantiron, and Corrosiron. They are generally corrosion resistant to a wide variety of media, but are used most generally for handling acids or acid salts. The alloys are not machinable, hence must be cast or ground to shape. They have high hardness and brittleness, and possess poor resistance to thermal shock.

The alloys are generally satisfactory in resisting sulfuric, nitric, acetic, lactic, and many other commercial acids in any concentration and at elevated temperatures. The corrosion rate in 10% sulfuric acid at 175 F is about 0.01 ipy (inches per year). They also satisfactorily resist sea water and mine water. They can be used to handle caustic solutions under moderately corrosive conditions, although some other common metals usually offer better advantages.

The alloy should not be used with halogen gases or their aqueous solutions, fused alkalies, hydrofluoric acid, crude phosphoric acid, concentrated hydrofluosilicic acid, sulfurous acid, hot hydrochloric acid, aqua regia, and solutions of heavy metal chlorides

THE 14.5% Si–3% Mo–Fe ALLOY. Resistance of the Si-Fe alloy to hot concentrated HCl is accomplished by the metallurgical addition of 3% Mo. This alloy is known as Durichlor. The corrosion rate in 30% HCl at 85 F is 0.01 to 0.02 ipy, at 150 F it is 0.02 to 0.035 ipy, and at 175 F it is 0.06 to 0.1 ipy. This alloy is not recommended for use with hot, heavy metal chloride solutions in concentrated acids, with mixtures of chlorine and steam, or with strong sulfuric or dilute nitric acids alternated with hydrochloric acid.

12. NICKEL AND NICKEL ALLOYS

NICKEL (see also Table 4) is more resistant under reducing conditions than under oxidizing conditions. For that reason, it can be used in service with sulfuric acid with only moderate attack, whereas it is not useful with nitric acid. It is outstandingly resistant to alkalies (except ammonium hydroxide) at any concentration or temperature.

Nickel is resistant to *fresh waters*, whether soft or hard. Corrosion in *sea water* is accompanied by pitting (0.07 to 0.09 in. maximum penetration in 3- to 4-year tests). Dissolved hydrogen sulfide accelerates the corrosion rate; resistance of nickel, nevertheless, is adequate in brine and natural waters containing this gas.

The corrosion rate of nickel in *sulfuric acid* is less in deaerated acids (0.003 ipy in hydrogen-saturated 5% sulfuric acid, 85 F) than in aerated acid (0.04 ipy in air-saturated 5% sulfuric acid, 85 F). The same is true in *hydrochloric acid*, the rates in 5% HCl being about twice those in 5% H_2SO_4. Nickel is not satisfactory for use with *crude phosphoric acid* or with *sulfurous acid*. In pure dilute *phosphoric acid* rate of attack is moderate, but in hot concentrated acid, corrosion is severe.

Organic acids at room temperature are only moderately corrosive in presence of nickel. At elevated temperatures, in highly aerated acids such as formic or acetic, corrosion may

Table 4. Nickel and Nickel Alloys

		Acids									
Metal	Best Resistance to Media That Are:	Sulfuric (Aerated)	Hydrochloric	Nitric	Phosphoric	Sulfurous	Acetic (Aerated)	H_2S	Ferric Chloride	Fatty Acids	Caustic Soda
Nickel	Reducing.	Less resistant than Cu-Ni, Pb, or Si-Fe alloys. If acid is boiling, use conc. under 10%.	Dilute only (<10%).	N.G.	N.G.	N.G.	0.01 ipy for 6% acid, room temperature.	O.K. for brines, and natural waters containing H_2S.	N.G.	O.K. (0.004 ipy at 440 F).	Excellent. For fused caustic, sulfur or SO_4 plus organic matter must be absent.
Monel 67% Ni, 30% Cu, 1.4% Fe, 1% Mn.	More resistant than Ni in reducing media. Better resistant than Cu in oxidizing media.	Up to 80% acid, <0.04 ipy.	Dilute only.	N.G.	N.G.	N.G.	<0.02 ipy at any concentration, room temperature.	Same as nickel	N.G.	O.K. (0.004 ipy at 500 F).	Good. (Nickel is better.)
Inconel 79.5% Ni, 13% Cr, 6.5% Fe.	Oxidizing.	Not as resistant as Monel. 0.06 ipy in 5% acid.	In dilute acid, same rate as Ni. In concentration > 10%, rate higher than for Ni.	O.K. in conc. above 20%, room temperature. Not as good as stainless steels.	Useful for all concentrations at room temperature.	N.G.	0.0008 ipy for 10% acid, room temperature.	O.K.	N.G.	O.K.	Good. (Nickel is better.)

be severe. Nickel is usefully resistant to *fatty acids* such as stearic and oleic at ordinary or elevated temperatures.

Nickel, which shows excellent resistance to *alkalies*, is used widely to handle caustic solutions where contamination and corrosion must be a minimum. It is second only to silver in this resistance. In fused alkalies it is essential that sulfides, or sulfates plus organic materials, be absent; otherwise intergranular penetration and weakening of nickel result. In handling 75 to 98% NaOH at high temperatures, nickel, if highly stressed, is subject to stress-corrosion cracking. Annealing at 1600 F for 3 to 5 min avoids any difficulty. "L" (low-carbon) nickel is better resistant than ordinary grades in fused caustic soda, particularly at welds.

Nickel is not resistant to aqueous ammonia.

Atmospheric Corrosion. Nickel remains reasonably bright and free from tarnish indoors, being superior to silver, copper, and brass in this respect. The metal becomes dull ("fogs") when exposed outdoors, a condition that can be avoided by a thin covering electro-deposit of chromium.

Electrodeposited on iron, a thickness of nickel equal to 0.5 mil is usually considered a satisfactory coating for indoor exposures, and 1.5 mil for outdoor exposures.

MONEL (NICKEL-COPPER) (see also Table 4). The composition of Monel is given nominally as 67% Ni, 30% Cu, 1.4% Fe, 1% Mn, 0.1% Si, 0.15% C, and 0.01% S. There are other Monels of the same basic composition to which are added aluminum, for example, to impart age-hardening characteristics, or sulfur for free machining. There are also casting compositions containing silicon added to increase hardness and impart resistance to galling. The following description applies only to Monel without additional elements, although in many environments one expects that the special Monels will behave comparably.

Monel is better resistant under reducing conditions than oxidizing conditions. It is highly resistant to corrosion by *fresh waters*, whether hot or cold (hence Monel hot-water boilers) and very resistant to *steam condensates*. The alloy is useful in *sea water*, especially under conditions of high velocity. In stagnant exposures, it tends to pit (0.005- to 0.016-in. maximum penetration in 3- to 4-year tests at Kure Beach, North Carolina).

In aerated *sulfuric acid* at 85 F, Monel is usefully resistant in concentrations of acid below 85%. The maximum corrosion rate of 0.04 ipy in the useful concentration range comes at 5% acid. Corrosion rates in hot *hydrochloric acid*, hot *phosphoric acid*, and hot *sulfurous acid* are high, as they are for nickel. Monel is resistant to unaerated *hydrofluoric acid* solutions including the anhydrous acid at low or high temperatures. It is usefully resistant to *acetic acid* at any concentration (less than 0.02 ipy at room temperature) and most common organic acids, including *fatty acids*.

The alloy is severely attacked by *nitric* or *nitrous acids*.

Monel, although attacked by concentrated *hypochlorite solutions*, is said to be satisfactory on continuous exposure to solutions containing less than 500 ppm of available chlorine. Resistance is increased by addition of sodium silicate or sodium phosphate (0.05 to 0.2%) to the hypochlorite solution.

Monel is resistant to *alkalies*, although inferior to nickel, especially in concentrated caustic soda at high temperatures. The alloy corrodes in aqueous *ammonia*.

Atmospheric Exposure. Monel remains reasonably bright indoors, but tarnishes outdoors, especially in industrial atmospheres. The corrosion rate is negligible over a long period of years.

INCONEL (Ni–Cr–Fe ALLOY) (see also Table 4). The nominal composition of Inconel is 79.5% Ni, 13% Cr, and 6.5% Fe. The alloy, in contrast to nickel and Monel, is better resistant to oxidizing than reducing media.

Inconel satisfactorily resists *fresh waters* and *steam condensates*. It is also resistant to *mine waters* containing ferric sulfate. In *sea water*, corrosion by pitting is likely to be pronounced, the tendency in this direction being greater than with Monel. In marine atmospheres, however, it is superior to Monel.

Resistance to *sulfuric acid* is not so good as with Monel. The corrosion rate increases with degree of aeration of the acid.

Although resistance to *phosphoric acid*, pure or crude, at room temperature is good, appreciable corrosion occurs in hot concentrated acid.

Inconel is resistant to *nitric acid* at room temperature above 20% concentration. However, the alloy is not so usefully resistant to this acid as are the stainless steels.

Resistance to many *organic acids* is satisfactory (although not in boiling concentrated acetic or formic acids). Resistance to *fatty acids* even at distillation temperatures (400 to 600 F) is excellent.

Inconel is resistant to *alkalies*, including concentrated NaOH at high temperatures. The corrosion rate in hot 75% NaOH at 275 F is reported to be 0.0013 ipy.

In hot alkaline solutions, *intergranular corrosion* has been reported. Corrosion of this kind presumably can be avoided by heat treatment at 1550 to 1600 F for approximately 10 hours or longer.

Inconel is better resistant to *sulfur* and *sulfides* at elevated temperatures than are Monel and nickel. It is also different in that it resists aqueous *ammonia*. Pitting occurs in *sodium hypochlorite* solutions, although the alloy demonstrates satisfactory resistance in concentrations used for textile bleaching or for sterilization.

Atmospheric Exposure. On indoor exposure, Inconel remains bright. Outdoors, tarnish occurs eventually when exposed to industrial atmospheres. The corrosion rate is extremely small.

HASTELLOYS. The Hastelloys are nickel-base alloys containing molybdenum and other alloying elements. Compositions of four Hastelloys are given in the accompanying table.

	Per Cent				
	Ni	Mo	Fe		Available Forms
Hastelloy *A*	60	20	20		Wrought and cast
B	65	30	5		Wrought and cast
C	59	17	5	14% Cr, 5% W	Hot-rolled plate, and cast
D	85			10% Si, 3% Cu, 2% Al	Cast

They are alloys essentially designed for resistance to heavy chemicals. Grades *A*, *B*, and *C* are resistant, and *D* moderately resistant, to *hydrochloric acid* in all concentrations at ordinary temperatures. Resistance drops off as temperature increases. For example, Grade *A* corrodes at the high rate of 0.26 ipy in 10% hydrochloric acid at the boiling point. At 155 F, however, the rate is 0.08 ipy, which is said to mark approximately the highest useful temperature for this grade used with hydrochloric acid.

Grade *B* is more resistant to hydrochloric acid, the rate being 0.034 ipy at 155 F and 0.012 ipy at the boiling point. Grades *C* and *D* in HCl corrode at higher rates than either *A* or *B*.

In *sulfuric acid*, Hastelloy *A* is suitable for handling acid in concentrations up to 50% and at temperatures including the boiling point. In concentrations over 50%, it is resistant up to about 155 F. Grade *B* is more resistant to boiling sulfuric acid than Hastelloy *A* in concentrations up to 60%. Grade *D* is economically resistant to all concentrations at temperatures including the boiling point. The alloy can be used for concentrating sulfuric acid by evaporation (corrosion rate = approximately 0.05 ipy).

Grade *C* resists oxidizing agents such as *nitric acid* (any concentration at room temperature, dilute only up to 150 F) and *chromic acid*, or mixtures with sulfuric acid. It is less resistant to most nonoxidizing acids than *A* or *B*.

The alloys resist *alkalies*, although there are less expensive metals available that are equally resistant. Hastelloy *C* is usefully resistant to *ferric chloride* and *cupric chloride* at room temperatures, but pitting eventually occurs, particularly at above room temperatures.

Grade *C* has excellent resistance to *sea water*. In a 6-year test at Kure Beach, North Carolina, the corrosion rate was only 0.00005 ipy, and no pitting occurred. The latter grade is also resistant to wet *chlorine* at room temperature and to *sulfur dioxide* up to about 155 F.

13. COPPER ALLOYS

The important copper alloys are the copper-zinc alloys, called *brasses*, and the copper-tin alloys, called *bronzes*. Copper and some copper alloys are especially useful in resisting natural waters, including sea water. The corrosion rate of copper in sea water is approximately 0.001 ipy. In common with high-copper alloys, copper is subject to little or no fouling by marine organisms in contrast to most metals and alloys. In soft waters and waters high in dissolved carbon dioxide, the corrosion rate is higher than in hard waters. The alloys resist *nonoxidizing* acids satisfactorily if dilute and, when dissolved oxygen or oxidizing salts are absent, in higher concentrations up to boiling temperatures. They corrode rapidly in *nitric acid*, or nonoxidizing acids containing heavy metal ions such as ferric or cupric.

The alloys have excellent resistance to *atmospheric attack*. In industrial atmospheres or near the ocean they form a characteristically protective green-colored patina after long periods of exposure.

Copper and copper alloys are satisfactory in many types of soils. In soils high in organic matter, or subject to seepage by waters high in dissolved carbon dioxide and organic acids, the corrosion rate may exclude copper as an economical material.

BRASSES. Dezincification. Brasses often corrode by dezincification. The tendency increases with zinc content of the alloy, and is accelerated in stagnant solutions. *Red brass* (85% Cu, 15% Zn) and alloys containing more than 85% Cu are largely immune to dezincification. This composition range including copper, however, is more susceptible to corrosion by solutions in motion (*impingement attack*). *Yellow brass* (70% Cu, 30% Zn) if alloyed with 1% tin (*Admiralty metal*) has increased resistance to dezincification. Furthermore, if a few tenths per cent of arsenic, antimony, or phosphorus is added, the alloy, called inhibited Admiralty metal, still further resists dezincification. This alloy is used widely for condenser tubes in sea water and fresh water service.

Aluminum brass contains approximately 2% aluminum, 76% copper, 0.1% arsenic, antimony or phosphorus, and the remainder zinc. This alloy, which is particularly resistant to high-velocity media, is used where impingement attack of the usual brasses is a factor. In stagnant chloride solutions, the alloy tends to corrode by pitting.

Galvanic Coupling. Copper and the brasses can be coupled to iron in cold fresh waters without serious *galvanic corrosion*. In hot water, the action is more rapid, and in sea water still more rapid, causing accelerated failure of the iron near the point of coupling. Coupling with stainless steels is usually acceptable, but coupling with aluminum or magnesium leads to serious attack of the light metals.

Season Cracking. If residual stresses are present in brasses after fabrication, the alloys corrode by cracking when exposed to an atmosphere containing dilute ammonia or amines. This type of failure is called *season cracking*. The presence of ammonia or amines appears to be necessary to failure of this kind.

Stresses sufficient to cause season cracking can be checked by the so-called mercury test in which a solution of mercurous nitrate in dilute nitric acid causes cracking within a few minutes if the alloy has not been properly annealed.*

Alloys containing 85% copper or more are more resistant to season cracking than alloys of lower copper content such as yellow brass or Muntz metal.

COPPER-TIN ALLOYS are called bronzes or tin bronzes, and when deoxidized with phosphorus are also known as *Phosphor Bronze*. The alloys are especially resistant to impingement attack. For high-velocity waters, it is desirable that the alloy contain at least 5% tin. Alloys containing more than 8% tin are usually used in the form of castings. The corrosion rate of the 5 to 8% tin alloy in sea water is approximately 0.001 ipy. The alloys have good resistance to corrosion fatigue and stress-corrosion cracking.

COPPER-SILICON ALLOYS (Everdur) contain 1 1/2 to 4% silicon. These are high-strength alloys behaving in corrosive media approximately like copper. They are more resistant to stress-corrosion cracking than the brasses.

COPPER-BERYLLIUM ALLOYS are high-strength, heat-treatable alloys also having corrosion resistance comparable to that of copper. They contain up to 2.75% beryllium and often 0.35% nickel. They have good resistance to corrosion fatigue and intergranular corrosion. The highly stressed alloys have been known to stress-corrosion-crack in ammonia atmospheres.

COPPER-NICKEL (CUPRO-NICKEL) ALLOYS contain 70% copper and 30% nickel, and sometimes 80% copper and 20% nickel. They are used for condenser tubes when corrosive conditions are especially severe, and when strength above atmospheric temperatures must be maintained. They resist impingement attack and are not subject to season or stress-corrosion cracking in normal applications.

14. ALUMINUM AND ALUMINUM ALLOYS

ALUMINUM is one of the metals exhibiting passivity, hence is better corrosion resistant in fully aerated or oxidizing media than in reducing or partially aerated environments. Chlorides and other halogen ions tend to break down passivity locally; hence aluminum in their presence may corrode by pitting. As with other passive metals, crevices and partially shielded areas must be avoided to avoid pitting at such areas. Of outstanding importance is serious lack of resistance to alkalies. Even in dilute alkalies, such as are leached from fresh Portland cement, aluminum is attacked.

Pure aluminum is satisfactory for handling distilled water, and resists action of steam up to 350 to 500 F. It corrodes in sea water with formation of pits.

ALUMINUM ALLOYS, in general, are less resistant than pure aluminum (2S). Pure aluminum, accordingly, has better resistance to saline atmospheres and solutions, as well as to dilute nonoxidizing acids such as acetic acid.

---

* The ASTM requirements for the mercurous nitrate test specify immersion for 15 min without cracking in a solution containing 100 grams per liter of mercurous nitrate and 13 ml of nitric acid (specific gravity 1.42).

Aluminum is satisfactorily resistant to acetic, lactic, tartaric, citric, and boric acids at room temperature. Formic and oxalic acids are definitely corrosive, as are hydrochloric, phosphoric, and perchloric acids. It is moderately resistant to sulfuric acid below 10% concentration, or in the concentration range of 95 to 100%.

Aluminum withstands oils, gasoline, and chlorinated solvents particularly *if dry*. Halogenated solvents in presence of moisture are corrosive.

Aluminum and its alloys should not be exposed to any alkali. They should be protected against concrete or lime, and any leachings from these materials.

Mercury and mercury salts must be rigidly excluded from contact with aluminum. They can cause perforation of aluminum sheet in very short time.

CLAD ALUMINUM ALLOYS. The better corrosion resistance of pure aluminum is made use of in *cladding* to protect stronger but inherently less corrosion-resistant alloys. They are called Alclad or Pureclad. If a pit penetrates the outer layer, perforation of the sheet is retarded by galvanic currents set up between outer and inner layers. The inner layer composed of, for example, a Duralumin-type alloy (17S or 24S) is noble with respect to the cladding, so that the core is cathodically protected by the cladding. Only after considerable portions of the cladding are corroded, which takes appreciable time, is the Duralumin core attacked. The protection is similar in mechanism to the protection of iron by a galvanized coating.

DURALUMIN. The Duralumin-type alloy if slowly cooled from the solution heat-treatment temperature of 920 F, or heated for a critical time above about 250 F, *corrodes intergranularly*. If the material is solution-heat-treated and quenched, this type of corrosion does not occur.

STRESS-CORROSION CRACKING. Some highly stressed aluminum alloys are subject to *stress-corrosion cracking* in certain mildly corrosive environments, such as sodium chloride solutions. Their relative susceptibility is often dependent on heat treatment. Commercially pure aluminum (2S), on the other hand, is resistant.

GALVANIC COUPLING. In the atmosphere and in many fresh waters, aluminum is cathodic to iron. In sea water, however, aluminum becomes more anodic and, therefore, cathodically protects iron by sacrificial corrosion. Cadmium and aluminum have similar potentials in many aqueous media, so that these two metals may be coupled together. Zinc is anodic to aluminum in most neutral or acid media, but the potential reverses in alkaline media, causing accelerated attack of aluminum.

In general, it is inadvisable to couple aluminum with copper or brass without due regard to accelerated corrosion that may result. Certain fresh waters, particularly soft waters, passing through copper pipe may pick up enough copper to damage aluminum subsequently.

BEHAVIOR IN SOILS. Aluminum buried underground in some types of soil may perforate by pitting. Alkaline or acid soils may cause rapid general attack. For long life, therefore, the metal should usually be protected by a suitable coating.

ATMOSPHERIC EXPOSURE. Of aluminum-base materials, 2S aluminum is among compositions showing lowest rate of attack in outdoor exposures. Corrosion rates, in general, are low. The use of clad alloys is recommended where perforation of the sheet must be avoided over as long a time as possible.

15. MAGNESIUM AND MAGNESIUM ALLOYS

Magnesium is active in the EMF series, but exhibits, nevertheless, good corrosion resistance in many environments. Degree of aeration of the environment is not a factor in the corrosion rate as with iron, corrosion proceeding largely by hydrogen evolution. Unlike aluminum, it satisfactorily resists attack by alkaline solutions.

Pure magnesium is considerably more resistant than commercial magnesium or its alloys. Pure magnesium, for example, corrodes in sea water at a rate of 0.012 ipy, whereas commercial magnesium corrodes at a rate 100 to 500 times higher.

Magnesium satisfactorily withstands hydrofluoric acid in concentrations above 2% and can be used to handle this acid. Some pitting may develop at the water line. Magnesium is also moderately resistant to pure chromic acid. It is not resistant to any of the mineral acids other than hydrofluoric and is attacked by most organic acids.

In alkaline solutions, magnesium corrodes at only a low rate. In dilute alkalies, attack is slight up to temperatures including the boiling point, and in concentrated alkalies, to somewhat lower temperatures. For example, the rate for 10% Al-0.2% Mn-Mg alloy in 50% NaOH at 140 F (21-day test) is only 0.001 ipy but this value increases above 140 F. Chlorides also increase the rate.

Magnesium satisfactorily resists many fresh waters, whether soft or hard. Traces of heavy metal salts such as cupric or ferric cause increased attack. The metal is resistant to ethylene glycol solutions. When magnesium is coupled to iron in ethylene glycol solutions at elevated temperatures, corrosion of magnesium increases, but can be inhibited by the addition of 0.5% NaF to the solution.

Magnesium satisfactorily withstands oils and gasoline, particularly *if dry*. If gasolines are displaced by water, those containing tetraethyl lead and ethylene dibromide cause increased tendency to attack especially at the water line. Organic acids in lubricating oils cause some corrosion.

Although denatured alcohol has little effect on magnesium, anhydrous methyl alcohol (methanol) causes serious attack. The reaction can be partially inhibited by addition of water, even ½%, greatly decreasing rate of attack. Phenol can be stored in magnesium-alloy drums. Fluorinated or chlorinated solvents do not produce corrosion except in the presence of water.

GALVANIC COUPLING. In a conducting solution such as 3% sodium chloride, all common metals in contact with magnesium act as cathode and, hence, accelerate attack of magnesium. The 5% Mg-Al alloy causes much less galvanic corrosion in comparison with other readily available metals.

Cadmium or zinc plating of the more cathodic metals such as iron or steel reduces galvanic corrosion to one-tenth the rate. A reduction in conductivity, for example a change from 3% sodium chloride to tap water, effects an even greater reduction.

Under conditions where the cathodic corrosion product is not continuously removed, or where the environment may become strongly alkaline, both magnesium and an amphoteric metal to which it is coupled, such as aluminum, may be attacked. Aluminum alloys containing appreciable magnesium such as 52S, 53S, or 56S are attacked least in this manner by chloride media.

One means of materially decreasing galvanic attack is to increase the distance between dissimilar metals by use of inset caulking compounds applied in a groove, machined either in the insert or in the magnesium alloy immediately adjacent. Nonconducting washers between dissimilar metals galvanically coupled will produce the same result.

Galvanic corrosion in the atmosphere is very much less than in aqueous media.

STRESS-CORROSION CRACKING. Magnesium alloys, if highly stressed, are subject to stress-corrosion cracking in water or the atmosphere. Tendency to cracking is especially severe in potassium chromate–sodium chloride solutions. The alloys are resistant to stress-corrosion cracking in solutions above *p*H 10.2, and also in fluoride solutions of any *p*H. Stress relief of fabricated parts reduces or eliminates tendency to failure of this kind.

The 1.5% Mn-Mg alloy, as well as the commercial casting alloys, are resistant to stress-corrosion cracking even though stressed up to the yield point. The magnesium alloys containing aluminum, zinc, and manganese, on the other hand, are sensitive below the yield point.

16. LEAD

In media that corrode lead more than slightly, the rate is usually proportional to the concentration of dissolved oxygen. Lead is outstandingly resistant to atmospheric attack and to attack by sea water. It withstands the action of many mineral acids such as sulfurous, phosphoric, chromic, and hydrofluoric (cold). Lead is particularly useful in handling sulfuric acid in any concentration and at any temperature. The rate of corrosion in 20% sulfuric acid at 75 F is approximately 0.007 ipy. Corrosion rates are higher when velocity of the acid succeeds in eroding the protective sulfate film.

Aerated acetic acid is very corrosive, even at room temperature. Acids from wood, especially green woods, can cause damage if lead is in contact with them or their vapors. Permissible woods for contact with lead are cedar or hemlock; otherwise lead should be protected by tar, asphaltum, paint, or lacquer.

Lead resists the action of alkalies only poorly. The rates are high enough so that use of other materials such as iron is more economical. The corrosion rate in dilute alkalies such as calcium hydroxide is sufficiently high, so that lead should not be brought into contact with fresh concrete or with water leaching from concrete.

GALVANIC CORROSION. Corrosion of iron is usually accelerated when coupled to lead in acid solutions, but in alkaline solutions the reverse is true and corrosion of lead is accelerated by iron. Corrosion of copper is accelerated by lead in strong acid solutions, but the reverse is true in alkaline solutions. It is usually satisfactory to couple the various commercial lead alloys in handling sulfuric acid and sulfates.

Galvanic corrosion of copper may occur, as for example with copper roofing, along a soldered seam if solder (Pb-Sn) is applied at such a temperature that a noble copper-tin intermetallic compound forms. If excessive heat is not used, corrosion of copper from this source is minimized.

TOXIC PROPERTIES. Lead, although a durable metal for handling fresh waters, may corrode sufficiently to render water questionable for drinking purposes because its salts are cumulatively toxic in small quantities. Distilled, soft, and carbonated waters are particularly aggressive in this respect. Likewise, alcoholic beverages and foodstuffs may accumulate dangerous quantities of lead if brought into contact with lead or its alloys.

ALUMINUM AND ITS ALLOYS

By W. P. Goepfert *

1. PROPERTIES OF ALUMINUM

Aluminum is one of the lightest of the metals used for structural purposes. The principal source is bauxite, a hydrated oxide of aluminum. In the production of aluminum, pure alumina (Al_2O_3), obtained by the treatment of bauxite ore with caustic soda, is reduced electrolytically to produce the metal. Silica and iron oxide impurities in the alumina will appear in the metal as silicon and iron. Purities as high as 99.95% have been produced for commercial application although 99.0 to 99.8% purity is more common for commercial usage.

RESISTANCE TO CORROSION. Aluminum possesses good resistance to corrosion under most atmospheric conditions. This characteristic is demonstrated by the successful use of high-purity aluminum (99.5% approx.) for transmission lines and outside bus bar installations. It is resistant to distilled water, many food products, fruit juices, milk and beer, sulfur dioxide, ammonia, and many other commercial items. It is readily dissolved by hydrochloric and hydrofluoric acids and by caustic solutions. The high resistance to corrosion of aluminum is due to the protective oxide film which is formed on its surface. In general, aluminum of the highest purity has the highest resistance to corrosion. Except for a few special cases, the presence of any other metals, either as impurities or alloying elements, tends to lower the resistance to corrosion.

PHYSICAL PROPERTIES. Some of the more important physical characteristics of high-purity aluminum are given in Table 1.

Table 1. Properties of High-purity Aluminum

Atomic weight	26.97
Density at 68 F	168.56 lb per cu ft
Density at melting point (solid)	159.20 lb per cu ft
Density at melting point (liquid)	148.59 lb per cu ft
Melting point	1220 F
Boiling point	3272 F
Coefficient of expansion per °F, 68–212 F	0.000 0132
Coefficient of expansion per °F, 68–572 F	0.000 0143
Coefficient of expansion per °F, 68–932 F	0.000 0154
Heat of vaporization	3510–3600 Btu per lb
Latent heat of fusion	167.36
Specific heat, 32–212 F	0.226
Thermal conductivity, Btu per hr per sq ft per °F per 1 in. thickness	1509
Electrical Properties	
Electrical resistivity at 20 C	2.688 microhms per cu cm
Electrical resistivity at 20 C (commercial conductors)	2.83 microhms per cu cm
Temperature coefficient of resistivity at 20 C	0.00403
Mechanical Properties	
Tensile strength	9000 psi
Yield strength (set = 0.2%)	3000 psi
Elongation in 2 in., %	60
Brinell hardness, 10-mm ball, 500-kg load	15
Modulus of elasticity	10,000,000
Modulus of rigidity (torsion)	3,800,000
Poisson's ratio	0.32
Miscellaneous Properties	
Crystallization shrinkage	6.6%
Reflectivity for white light	90%
Magnetic susceptibility (cgs units)	0.000 000 58
Compressibility (change in volume per megabar pressure)	0.000 0014

2. CAST ALUMINUM ALLOYS

Pure aluminum does not cast easily, nor does such a casting have attractive commercial properties. Alloys of aluminum, however, have been formulated to produce the desired commercial properties and to be compatible with the particular casting method for which they are intended. Although there has been some small production of aluminum castings by such methods as plaster mold casting, precision investment casting, and centrifugal casting, the three most significant methods are sand casting, permanent mold casting, and die casting. They are discussed in Aluminum Alloy Casting, Section 19, Article 18.

CHEMICAL COMPOSITION AND PHYSICAL PROPERTIES. The nominal chemical compositions, densities, and typical mechanical properties of the majority of the more widely used sand-casting alloys and tempers are contained in Table 2. Permanent mold-casting alloys are listed in Table 3, and die-casting alloys in Table 6, p. 4-81.

HEAT-TREATMENT DESIGNATIONS. Aluminum Company of America's basic heat treatment designations for the conditions of the casting alloys discussed herein are T2, T4, T5, T6, and T7. Suffix numbers affixed to these indicate certain variations within the basic type of treatment to obtain desired characteristics. The basic T2 treatment is that generally classified as an annealing treatment. It consists of heating at an intermediate temperature to relieve internal stresses and to stabilize dimensions. In order to obtain the potential high properties of the heat-treatable alloys, the castings must first be given a

* Tests made on separately cast test bars without machining the surface.

† Yield and ultimate strengths are pounds per square inch and elongation is percentage in 2 in.

‡ The properties shown for temperatures of 300 F and higher also apply to the T6 condition.

solution heat treatment. This treatment, identified as T4, provides for heating the material at a sufficiently high temperature to obtain solution of the soluble constituents and for quenching to retain a large part of the solute in solution. A considerable increase in properties is obtained by this treatment. For most alloys, however, a subsequent aging treatment at a low temperature to effect precipitation of the dissolved constituents will further increase the properties. Solution treatment followed by such aging is designated as T6. Treatments consisting of aging, subsequent to solution treatment, under such conditions as to carry the hardness of the alloy beyond maximum and to control growth and residual stress bear the designation T7. Material in the as-cast condition when given an aging treatment without a previous solution treatment will experience an increase in properties above those in the as-cast condition. This treatment, which is known as T5, improves mechanical properties, reduces internal stress, and increases the dimensional stability at elevated temperature.

ALUMINUM-ALLOY CASTINGS AT HIGH TEMPERATURE. Strength and hardness of pure aluminum decreases progressively with rising temperature. Certain alloys, however, maintain their properties at elevated temperatures better than others and are therefore used for high-temperature applications. Properties of some of the casting alloys are given in Table 4. The values in this table are the lowest strength during 10,000 hours of heating at testing temperature. Room temperature properties after heating will be higher than the properties at an elevated temperature.

ALUMINUM-ALLOY CASTINGS AT LOW TEMPERATURES. In general, strength and hardness of aluminum alloys remain unchanged or improve at subzero temperatures.

3. WROUGHT ALUMINUM ALLOYS

CLASSIFICATION. Wrought aluminum alloys may be classified as: (1) nonheat-treatable or those in which the obtainable properties are produced by strain hardening; (2) heat-treatable or "strong alloys" in which the obtainable properties are produced by heat treatment alone or in combination with a certain amount of strain hardening. In general, higher properties are obtainable with alloys of Class 2. The Aluminum Company of America designates its wrought alloys by the alloy number followed by a temper or heat-treatment designation. The letter "S" used in terminating the alloy number merely indicates that the alloy is in wrought form as differentiated from cast form.

TEMPER DESIGNATIONS. With alloys of the nonheat-treatable type, material in a definite strain-hardened state is indicated by a temper designation representing a particular set of mechanical properties produced by a particular type of treatment for the pertinent alloy.

Formerly, these temper designations ranged with increasing amounts of strain hardening from "O" for annealed material to "H" for hard temper, intermediate tempers being designated as fractions of H. This system of nomenclature, however, has been found too inflexible to permit differentiation of certain processing variables, and the Aluminum Company of America has introduced a more complete system. In the new system O continues to designate annealed material for all wrought alloys. The strain-hardened conditions are indicated basically by H1 when the properties are the result of strain hardening only, H2 when strain hardened and partially annealed, and H3 when strain hardened and stabilized. These basic designations are followed by one or more digits to indicate the final degree of strain hardening remaining in the material. For example, 2S-$^1/_2$H now becomes 2S-H14 or 2S-H24, depending on whether it was produced by strain hardening alone or by strain hardening and partial annealing, and 52S-$^1/_2$H (strain hardened and stabilized) becomes 52S-H34.

Similarly, the old system of nomenclature for the heat-treatable alloys, where basically "W" indicated the solution heat-treated temper and "T" the solution heat-treated and aged temper, has been found inadequate to differentiate between all the pertinent processing differentials recognized in the industry today. The new system introduced by the Aluminum Company of America for these alloys is basically:

-W	Solution heat treated—unstable temper.
-T3	Solution heat treated and then cold worked.
-T4	Solution heat treated and naturally aged to a substantially stable condition.
-T5	Artificially aged only.
-T6	Solution heat treated and then artificially aged.
-T8	Solution heat treated, cold worked, and then artificially aged.

Subsequent digits are used to indicate variations within the above basic classifications. For example, 24S-T becomes 24S-T3 or T4, depending on whether the material is cold worked after solution heat treatment or not.

[*] The properties given in this table are generally applicable to all wrought products made in these alloys, although some variation with product and direction of testing will occur.

[†] Average modulus of elasticity in tension and compression. Tensile modulus will be approximately 1% lower and compressive modulus approximately 1% higher than this average value.

[‡] Endurance limit values are based on 500,000,000 cycles of completely reversed stress using the R. R. Moore type of machine and specimen.

[§] Alloy numbers, except SAE, refer to designations used by the Aluminum Company of America. Suffix indicates heat treatment applicable.

[‖] Yield-strength values determined from stress-strain curve as the point where the curve departs 0.2% from the initial modulus line produced. Compressive yield strength is the same as tensile yield strength for all practical purposes.

[¶] Alclad 24S has a primary and secondary modulus as a result of the aluminum cladding. Primary modulus is 10,600,000 for all gages. Secondary modulus for gages 0.064 in. and greater is 10,100,000, for gages less than 0.064 in., 9,600,000. Primary modulus effective for approximately the first 10,000 psi.

[**] Alclad 75S has a primary and secondary modulus as a result of the aluminum alloy cladding. Primary modulus is 10,400,000 and the secondary modulus is 9,600,000 for all gages. Primary modulus effective for approximately the first 10,000 psi.

CHEMICAL COMPOSITION AND PHYSICAL PROPERTIES. The nominal chemical compositions, densities, and typical mechanical properties for the majority of the more widely used wrought alloys and tempers are given in Tables 5 and 6 for nonheat-treatable and heat-treatable alloys, respectively.

ALUMINUM ALLOY WROUGHT PRODUCTS AT HIGH TEMPERATURE. In general wrought-aluminum alloys will experience a decrease in strength when heated above a certain critical temperature. For certain alloys which precipitation-harden during heating, there will be a loss in strength in the very early stages of heating followed by an increase in strength which eventually will drop off to a stabilized condition with increasing heating times. Properties of some of the wrought alloys at elevated temperatures are given in Tables 7 and 8 for the nonheat-treatable and the heat-treatable alloys, respectively. The values in these tables are the lowest strengths that will be obtained during 10,000 hours of heating at the test temperature. Room-temperature properties after heating will in general be higher than the properties at an elevated temperature.

* Yield and ultimate strengths are pounds per square inch and elongation is percentage in 2 in.

ALUMINUM-ALLOY WROUGHT PRODUCTS AT LOW TEMPERATURE. In general, strength and hardness of aluminum alloys remain unchanged or improve at subzero temperatures.

EFFECTS OF COLD WORKING. Many commercial wrought products of aluminum and its alloys are supplied in various tempers determined by the amounts of cold working given the products after final annealing. See R. L. Templin in *The Aluminum Industry*, Vol. II, Chapter xix, p. 396, and *Transactions* of the American Institute of Mining and Metallurgical Engineers, Institute of Metals Division, 1930, p. 466, for a discussion of the effect of cold working on the physical properties of aluminum and its alloys. The formulas and diagrams which follow are taken from these references.

* Yield and ultimate strengths are pounds per square inch and elongation is percentage in 2 in.

Cold working is defined as the change in cross-sectional area of the metal resulting from rolling, forging, drawing, or extrusion at about room temperature, i.e., 60 to 80 F. Generally, sheet or plate may be considered to change in cross-sectional area solely from the reduction in thickness of the product, since there is little change in width during rolling.

If aluminum and its alloys are worked at temperatures above room temperature, the effects of cold working are less in proportion to the amount of work done than when they are worked at room temperature. Conversely, the work done at temperatures below room temperature is more effective than the same amount of work at room temperature.

Cold working is expressed as the percentage change in the original cross-sectional area (commonly called reduction) as follows:

In general,

$$C = \frac{100(A - a)}{A}$$

where C = amount of cold working, %; A = initial area of material in properly annealed condition; a = area of the cold-worked material.

For sheet,

$$C = \frac{100(t_0 - t_f)}{t_0}$$

where t_0 = initial thickness of the material and t_f = final thickness.

The effect of cold working on the tensile strength of wrought aluminum and its alloys is shown by $TS = TS_0(1 + 0.9R^2)$, where TS = tensile strength, psi; TS_0 = tensile strength of the properly annealed material; R = reduction in area expressed as a decimal.

The average tensile strengths of the annealed commercial alloys that are fabricated into products of various intermediate tempers by cold working are as given in Table 5.

The yield strength of aluminum and its alloys is defined as the stress corresponding to a limiting permanent set of 0.2%. In properly annealed wrought metal this value will be approximately one-third the ultimate tensile strength. For all the other tempers of a cold-worked product, the yield strength will vary from 75 to 95% of the ultimate tensile strength.

Elongation is affected considerably both by the size and shape of the test specimen, as well as by the ductility.

The relation between tensile strength and Brinell hardness of wrought aluminum and its alloys is approximately TS = 575 × Brinell hardness number.

Figure 1 shows graphically the effects of cold working on the physical properties of aluminum and its alloys.

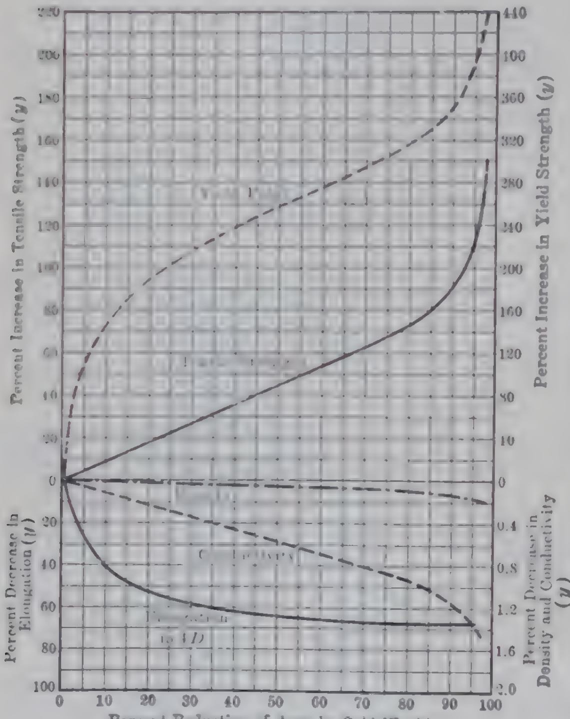

FIG. 1. Effects of cold working on the physical properties of aluminum.

4. DESIGN CONSIDERATIONS AND ALLOY SELECTION

WORKING STRESSES. Selection of the working stresses for a particular application is a function of the discretionary ability of the design engineer founded on experience in the particular field of endeavor. Small amount of reflection is necessary to see that it is not practicable to establish tables of working stresses for the various alloys and tempers or heat treatments that would be suitable for all applications and fields of design. Such values must be selected on the basis of as complete a knowledge of the operating conditions of the part being designed and of the properties of the material being used as it is practicable to obtain. The more complete and accurate this knowledge, the smaller can be the factor of safety reliably employed in establishing the working stress for the particular application.

For aircraft design data reference should be made to *ANC Bulletin ANC-5* (Strength of Aircraft Elements), issued by the Air Force-Navy-Civil Sub-committee on Aircraft Design Criteria; it can be purchased from the Superintendent of Documents, Government Printing Office, Washington 25, D.C. As a general comparison of the use of aluminum in ordinary structural applications, allowable unit tensile stresses of 16,000 psi for 61S-T6 and of 21,000 psi for 14S-T6 are used for applications where a stress of 18,000 psi is used for ordinary grade of carbon steel. To supplement the information given in the previous sections, additional information is presented here as an aid to the designer in his selection of material and allowable working stresses for a particular application. Table 9 contains typical values of rotating beam fatigue strength of some of the wrought alloys at five different cycle levels for complete reversal of stress. Table 10 contains typical values of direct tension-compression fatigue strength of some of the wrought alloys at five different cycle levels for different conditions of minimum stress. Table 11 contains column formulas for ultimate strength for various wrought-aluminum alloys.

Table 9. Rotating-beam Fatigue Data *

61S-T6	T	31,000	22,500	17,500	15,000	13,500

* Values given were determined by testing 0.3-in. diameter machined specimens in R. R. Moore's rotating-beam fatigue machines. They represent extreme fiber stresses which such specimens will withstand in completely reversed flexure.

† All values of stress in pounds per square inch.

‡ Values given for 500,000,000 cycles are commonly known as endurance limits.

ALLOY SELECTION. As for selecting working stresses, the design engineer's most reliable basis for selection of alloy is experience. The alloy that has been found very successful in a closely similar application is in most instances the one best suited to a particular application. This generalization, however, must be tempered to the extent of not interfering with the utilization of new and improved alloys designed to supplant some of the older more popular alloys. Some general characteristics of the various alloys and a few typical applications are presented here as an indication of where some experience has been acquired with the pertinent material. Composition and properties of the sand-casting alloys are given in Table 2, p. 4-03; of permanent mold casting alloys in Table 3, p. 4-04; of die-casting alloys in Table 6, p. 4-81; of wrought alloys in Tables 5 and 6, pp. 4-07 and 4-08.

Casting Alloys. 13 alloy is a die-casting alloy having excellent castability and resistance to corrosion. It finds application in castings having large thin-walled sections and intricate designs. Typewriter frames, outboard motor pistons, and instrument cases are typical applications.

43 alloy has limited application in die castings requiring above average ductility. The alloy has excellent resistance to corrosion and weldability. It is also used extensively in sand and permanent-mold castings where these characteristics are desired. Cooking utensils, food-handling equipment, marine and architectural fittings, and miscellaneous thin-sectioned castings are typical applications.

85 alloy is a general purpose die-casting alloy having a good combination of strength and ductility. Brackets, levers, and frames having thick sections are typical applications.

108 and A108 alloys are used where good casting characteristics, pressure tightness, and weldability are required. Ornamental grilles, manifolds, and valve bodies are typical applications.

113, C113, and 212 alloys are used where good casting and pressure tightness characteristics and very good machinability are required. Of these alloys C113 is the most popular for permanent-mold casting

* Values given were determined by testing 0.2-in. diameter machined specimens in direct stress fatigue machines and represent uniformly distributed stresses which such specimens will withstand under repeated axial loads.

† All values of stress in pounds per square inch. Stresses considered algebraically: plus (+) means tension, minus (−) means compression.

Automotive cylinder heads, internal-combustion engine timing gears, washing machine agitators, and miscellaneous general-purpose castings are typical applications.

A132 alloy is used where good high-temperature strength, low coefficient of thermal expansion, and good wear resistance are required. Automotive and diesel pistons and pulleys and sheaves are typical applications.

138 alloy is used where high hardness at elevated temperatures and good polishing characteristics are desired. The major application of this alloy is sole plates for electric flat irons.

195 and B195 alloys are used where a good combination of mechanical properties, fair castability, and good machinability is required. Aircraft fittings, aircraft wheels, railroad car seat frames, mechanical equipment parts, and flywheel and gear housing are typical applications.

214, A214, B214, and F214 alloys are used where excellent resistance to corrosion and tarnish is required. Dairy and food-handling equipment, architectural applications, cooking utensils, and fittings for chemical and sewage use are typical applications.

218 alloy is a die-casting alloy used in applications requiring exceptional mechanical properties, resistance to corrosion and finishing characteristics. Aircraft brake shoes, cylinder blocks for outboard motors, fittings, and brackets for marine application are typical applications.

220 alloy is used where very high strength and elongation, excellent machinability, and resistance to corrosion are required. Aircraft fittings, railroad and truck frame and bolster parts, and miscellaneous castings requiring strength and shock resistance are typical applications.

319 alloy is used where good castability and a good combination of mechanical properties are desired. It is used today for many applications formerly using 112, 113, C113, and 212 alloys. Piano plates, internal-combustion engine crankcases, oil pans, gasoline and oil tanks, and miscellaneous pressure tightness applications are typical applications.

Table 11. Ultimate Strength Formulas for Axially Loaded Aluminum-alloy Columns

(Representative of material having the typical properties shown in Tables 5 and 6)

Alloy and Temper	Old Temper Designation	Typical Compressive Yield Strength, psi	For KL/r less than C	C	For KL/r greater than C
3S-O	O	6,000	$\frac{P}{A} = 6{,}200 - 18\frac{KL}{r}$	194	$\frac{P}{A} = \frac{102{,}000{,}000}{\left(\frac{KL}{r}\right)^2}$
3S-H12	1/4 H	15,000	$\frac{P}{A} = 16{,}100 - 78\frac{KL}{r}$	138	
3S-H14	1/2 H	18,000	$\frac{P}{A} = 19{,}600 - 105\frac{KL}{r}$	125	
3S-H16	3/4 H	21,000	$\frac{P}{A} = 23{,}200 - 135\frac{KL}{r}$	115	
14S-T6	T	58,000	$\frac{P}{A} = 74{,}800 - 780\frac{KL}{r}$	64	
17S-T4	T	37,000	$\frac{P}{A} = 43{,}800 - 350\frac{KL}{r}$	83	
24S-T3	T	46,000	$\frac{P}{A} = 56{,}600 - 510\frac{KL}{r}$	73	
52S-O	O	14,000	$\frac{P}{A} = 15{,}000 - 70\frac{KL}{r}$	143	
52S-H32	1/4 H	26,000	$\frac{P}{A} = 29{,}400 - 192\frac{KL}{r}$	102	
52S-H34	1/2 H	29,000	$\frac{P}{A} = 33{,}200 - 230\frac{KL}{r}$	96	
52S-H36	3/4 H	34,000	$\frac{P}{A} = 39{,}800 - 302\frac{KL}{r}$	88	
53S-T4	W	20,000	$\frac{P}{A} = 22{,}000 - 124\frac{KL}{r}$	118	
53S-T6	T	33,000	$\frac{P}{A} = 38{,}400 - 287\frac{KL}{r}$	90	
61S-T4	W	21,000	$\frac{P}{A} = 23{,}200 - 135\frac{KL}{r}$	115	
61S-T6	T	39,000	$\frac{P}{A} = 46{,}600 - 384\frac{KL}{r}$	81	

Notes. Members are assumed to be compact enough so that no local failure will occur. P/A = ultimate strength of column, pounds per square inch, L = unsupported length of column, inches, r = corresponding radius of gyration, inches; K = 0.5 for both ends fixed; K = 1.0 for both ends hinged

355 alloy is used where good castability, weldability, and pressure tightness are required. Aircraft supercharger covers and impellers, fuel pump bodies, air compressor pistons, water-cooled cylinder heads, liquid-cooled engine crankcases, and blower housings are typical applications.

356 alloy is used where excellent castability and good weldability, pressure tightness, and resistance to corrosion are required. Aircraft pump parts, marine transmission cases, aircraft fittings and control parts, liquid-cooled engine crankcases and aircraft, truck and bus wheels are typical applications.

360 and A360 are cold-chamber die-casting alloys used in large thin-walled applications and intricate designs where good properties and resistance to corrosion are desired. Cover plates and instrument cases are typical applications.

380 and A380 are general-purpose die-casting alloys having better castability than 85 alloy.

406 alloy has excellent resistance to corrosion but poor castability. It has found some application in pipe and tank fittings.

750 is a bearing alloy that has found use in miscellaneous internal-combustion engine-bearing and bushing applications.

Wrought Alloys. 2S and 3S alloys are used where good formability, high resistance to corrosion, and good weldability are governing factors. 3S is preferred where higher strength is desired. Gasoline and oil tanks, trim in transportation equipment, cooking utensils, food and chemical handling, and storage equipment are typical applications.

Alloy 11S is used where excellent machinability and good strength are required. Screw machine parts and miscellaneous forgings requiring considerable machining are typical applications.

Alloy 14S is used where high strength, relatively good formability, and high hardness are required. Heavy-duty forgings, power shovel booms, aircraft fittings, and structural applications are typical.

Alloy 17S is currently not used other than for rivets and screw machine parts. It has been largely superseded by 14S and 24S alloys.

Alloy 18S is used for forgings requiring good strength at elevated temperatures. Cylinder heads and pistons are typical applications.

Alloy 24S is used in applications where higher strengths than 17S are desired. Aircraft structures, nails, rivets and hardware, and miscellaneous structural applications are typical.

Alloy 25S is used for forgings where good forgeability and fairly high strength are required. Airplane propellers, link rods, supercharger impellers, and jet engine compressor wheels are typical applications.

Alloy 32S is used for forgings requiring good forgeability and low coefficient of thermal expansion. Forged pistons are the major application.

Alloy A51S is used for forgings where very good forgeability, good strength, and good resistance to corrosion are required. Crankcases, fan parts, machine and automotive parts are typical applications.

Alloy 52S is used in applications where good workability, very good resistance to corrosion, high fatigue strength, and moderate static strengths are desired. Aircraft fuel and oil lines, fuel tanks, miscellaneous marine and transportation applications are typical.

Alloy 56S is used in applications where good workability, very good resistance to corrosion, and moderate strength are desired. Petroleum-refining equipment, beer barrels, miscellaneous naval construction, and architectural applications are typical.

Alloy 61S is used in applications where good strength, good workability, and very good resistance to corrosion are required. Aircraft landing mats, pontoon boats, canoes, furniture, vacuum-cleaner tubes, and transportation equipment are typical applications.

Alloy 63S has its major application in architecture, where a bright silvery anodized finish is desired.

Alloy 75S is used where very good strength and good resistance to corrosion are required. Aircraft structural parts are currently the major field of application for the alloy.

FABRICATED PRODUCTS. Although aluminum and its alloys are produced in the wrought form as sheet and plate, foil, bar, rod, shapes, wire, tubing, and forgings, not all the wrought alloys are commercially produced in all these products. Availability of the alloy desired in the form and size contemplated should be determined before proceeding too far with design. Plate, sheet, wire, and tubing are commercially available with a clad coating of higher resistance to corrosion and of higher solution potential than the core material. The clad coating is integrally bonded to the core and is of such thickness as to retain maximum physical properties consistent with adequate protection of the core.

RESISTANCE TO CORROSION OF ALUMINUM ALLOYS. Resistance to corrosion of a material is a characteristic of major importance to the designer. Because of the inability of expressing this characteristic in measurable terms of general applicability, there is no substitute for experience in uses under similar operating environments, and the advice of specialists in the field should be sought in selection of alloys. As a guide to the relative merits of the alloy systems composing the more commonly used aluminum alloys, the following brief analysis is presented.

Aluminum-manganese Alloys. The wrought aluminum-manganese alloy 3 S, because of its excellent resistance to corrosion, has been used for many years in a wide variety of applications. Casting alloy 406, although not used extensively, has a comparable resistance to corrosion.

Aluminum-magnesium Alloys. Wrought alloys and cast alloys having maximum magnesium contents of about 5 and 10% respectively, have excellent resistance to corrosion, and for this reason the wrought alloys 52S and 56S and the cast alloys 214, 218, and 220 have been used under relatively severe conditions of exposure without protection. The cast alloy A214, which contains additions of zinc, as well as alloys B214 and F214, which contain additions of silicon, have a resistance to corrosion very closely approaching that of the foregoing alloys.

Aluminum-magnesium Silicide Alloys. Alloys of this system having magnesium and silicon contents in the proportion required to produce Mg_2Si have excellent resistance to corrosion, comparable to that of 2S, 3S, and 52S. Wrought alloys 53S, 61S, and 63S fall within this category. Alloy A51S has an excess of silicon, which results in a slight reduction in resistance to corrosion in the heat-treated and aged conditions.

Aluminum-silicon Alloys. The binary alloys 13 and 43, and those of this group such as 356, 360, and A360 which contain magnesium additions, possess excellent resistance to corrosion. Alloy 355, which contains additions of copper, and alloy A132, which contains additions of nickel and copper, have resistance to corrosion closely approaching that of the other alloys included in this system.

Aluminum-copper Alloys. With proper heat treatment, the commercially available wrought alloys of this system such as 11S, 14S, 17S, 24S, and casting alloys 113, C113, 142, 195, and 212 have good resistance to corrosion but should be given a protective treatment when used outside. Wrought alloys 18S and 25S have lower resistance to corrosion than 17S and 24S, but considerable quantities have been used in aircraft engine and propeller applications, respectively, with satisfactory results.

Aluminum-copper-silicon Alloys. Some of the casting alloys contain both copper and silicon in relative percentages to justify grouping in another system. Of this system, alloys 85, 108, A108, 138, B195, 380, and A380 can be classed with the aluminum-copper alloys with regard to resistance to corrosion.

Aluminum-zinc-magnesium Alloys. 75S alloy, which is of this system, has a resistance to corrosion comparable to that of other high-strength aluminum alloys such as 24S.

Clad Alloys. For applications where the mechanical properties of some of the wrought alloys are desired but better resistance to corrosion is needed, or where good resistance to perforation is desired, clad products have been developed. Clad 3S, 14S, 24S, and 75S are examples of such products. These products have excellent resistance to corrosion, the cladding also offering protection against corrosion at the cut edges or small areas of exposed core material by electrochemical sacrifice. Sprayed aluminum coatings are sometimes used to protect castings and forgings by the same principle.

5. HEAT TREATMENT OF ALUMINUM ALLOYS

SOLUTION HEAT TREATMENT. A change in properties as a result of heat treatment of aluminum alloys usually is associated with a change in solubility of one or more of the alloying ingredients with change in temperature. Thus, over 5% copper is soluble in solid aluminum just below the melting point of the eutectic; at room temperature the solubility is well below 1%. If aluminum alloys containing about 4% copper are heated to a temperature slightly below the melting point of the eutectic, the copper will dissolve in the aluminum at that temperature. If the alloy then is cooled quickly to a low temperature, it becomes supersaturated with copper at the lower temperature. This treatment is known as a solution heat treatment. In certain alloys, like 17S or 24S, the supersaturated solid solution breaks down at ordinary temperatures, precipitating minute particles of the solute. This precipitation, known as aging, changes the physical properties.

In carrying out the solution heat treatment, temperature must be controlled closely. Thin pieces of wrought metal may be heated to the proper temperature and held there only a short time before cooling, with good results. The operation may be carried on in a hearth or pit furnace or in a bath of fused niter. Castings and large wrought pieces, however, must be held at the heat-treating temperature for considerable periods of time, and automatic temperature control is practically necessary. Quenching after the proper heating cycle should be as rapid as practicable. Wrought products are usually quenched in cold water whereas castings and complicated forgings are more commonly quenched in hot water to minimize internal stress and avoid distortion.

PRECIPITATION HEAT TREATMENT. In certain alloys, the precipitation changes produced in the solution heat-treated material at ordinary temperatures are insufficient for the requirements, and the desired results are effected by treatment at elevated temperatures. Such a treatment is known as precipitation heat treatment or artificial aging. In general, room-temperature aging will increase hardness and strength of solution heat-treated aluminum alloys. The same is true of the precipitation heat treatment, if it is not carried too far. The latter is capable of producing a wide range of properties without change in the alloy composition. It is sometimes used on material in the "as fabricated" condition, without intermediate solution heat treatment, taking advantage of the partial solution of the alloying constituent in this condition.

The precipitation heat treatment may be effected by heating in pressure vessels with steam or by heating in baths, such as oil, or in furnaces heated by oil, gas, or electricity. The temperature should be well controlled for best results, and, if an air furnace is used, circulation is desirable. The rate of cooling after the precipitation heating usually is not an important factor.

Other effects of heat treatment of aluminum alloys are the removal of internal strains, stabilization of dimensions of parts used or processed at elevated temperatures, and changes in particle size of constituents such as silicon, which may be present in amounts greater than can be dissolved in solid aluminum even at the eutectic temperature.

6. MACHINING OF ALUMINUM

Aluminum and its alloys may be machined readily. In many instances, satisfactory results may be obtained with tools ordinarily used for steel, provided they are sharp and in good condition. Because of the inherent machining characteristics of aluminum, better results may be obtained, however, when certain changes in tool shape and machining practice are observed. Generally speaking, aluminum and most of its alloys have similar machining characteristics.

Cutting tools for aluminum resemble those for cutting hard wood in many respects. It should be emphasized that the cutting edges must be ground to a sharp included angle, must be keen, and should be provided with smoothly finished surfaces. The tools generally are ground with fine abrasive wheels, supplemented by hand stoning with an oilstone to give the desired finish of the surfaces and edges.

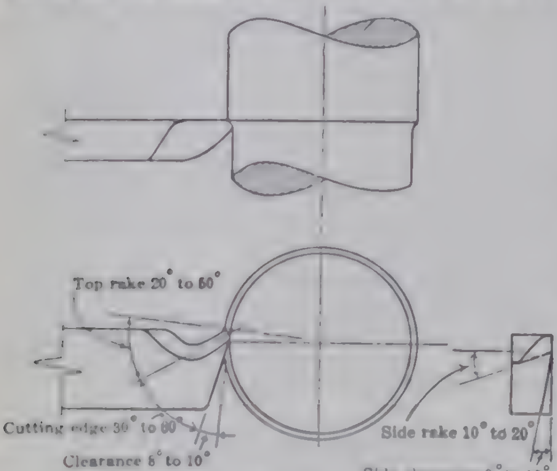

Fig. 2. Lathe tool for turning aluminum.

LATHE, SHAPER, AND PLANER TOOLS. Figures 2 to 4 illustrate typical lathe and planer tools for machining aluminum. Attention is called to the unusually large amount of top and side rake.

MILLING CUTTERS for aluminum should be of the coarse-tooth spiral type, with a considerable amount of top rake on the cutting edges. The more recent helical milling cutters, designed primarily for machining steel, work especially well with aluminum and its alloys, if the cutting edges are provided with suitable top rake.

DRILLS. Ordinary twist drills work fairly satisfactorily in aluminum if properly ground with keen edges, but a better type of drill is one with more twist to the flutes. Both types are illustrated in Fig. 5. Fairly high speeds may be employed if ample cutting compound is used. (See also Section 23, Articles 23 and 24.)

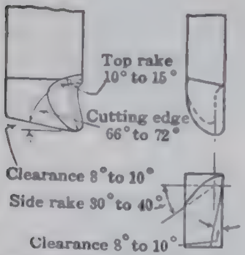

Fig. 3. Planer tool for roughing aluminum.

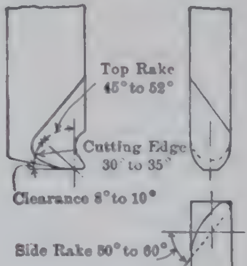

Fig. 4. Planer tool—finishing.

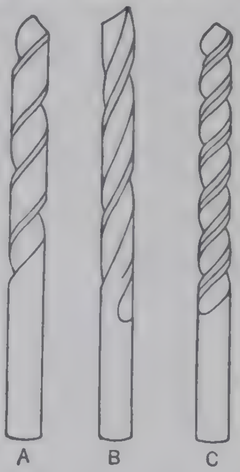

Fig. 5. Three types of twist drills, 3/8 in. diam. *A*, Single flute twist-drill, 40° spiral angle. *B*, Double flute or standard twist-drill, 24° spiral angle. *C*, Special double fluted twist drill, 47° spiral angle.

REAMERS of the spiral fluted type produce the best results for reaming holes in aluminum.

TAPS, generally designated "gun" taps or spiral pointed taps (Fig. 6), which have a short spiral ground at the nose, work very satisfactorily in aluminum, especially for through holes where the cuttings can be pushed ahead. Better results may be obtained with spiral fluted taps (Fig. 7), now offered by a number of manufacturers of small tools.

SAWING. The shapes of saw teeth should be patterned after those of the cutting tools described in the foregoing, so far as practicable. Teeth usually should have some top rake or hook, the amount depending on the type of saw, although very little can be used with band saws or circular saws where the work is fed by hand. The teeth should be comparatively coarse, with curved gullets, free from sharp corners and burrs or scratches which are likely to pick up cuttings.

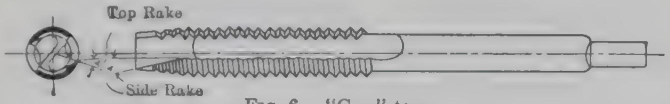

FIG. 6. "Gun" tap.

Circular saws for aluminum may be operated at peripheral speeds of about 10,000 ft per min. Speeds of about 5000 ft per min are recommended for band saws.

A cutting lubricant or coolant is desirable, and for heavy work is necessary. Mineral-base lubricating oils thinned with kerosene and, in some instances, soluble-oil cutting compounds have been found satisfactory.

Hand hack-saw blades of the "wavy-set" type work especially well with aluminum.

FILES. Some of the coarse-tooth files with top and side rake to the cutting teeth work well on aluminum.

CUTTING SPEEDS AND FEEDS. A wide range of cutting speeds and feeds may be used in machining aluminum and its alloys. Roughing cuts may be quite heavy. For highly finished surfaces, cuts only a few thousandths of an inch deep may be used, provided the cutting tools are properly shaped and finished. Speeds necessarily depend on such factors as the kind of machining operation, type and condition of machine tool, and kind of cutting material. Conventional machine tools can generally be operated at their maximum speeds in machining aluminum and in certain special-purpose machines; cutting speeds as high as 20,000 ft per min have been used to advantage.

CUTTING LUBRICANTS. Some of the alloys of aluminum have been machined successfully without any lubricant or coolant, with tools of the form described, but the use of some form of compound is desirable for best results. The soluble cutting oils usually are satisfactory for milling, sawing, and drilling. For such operations as turning, shaping, and tapping, a mixture of equal parts of lard oil and kerosene generally is recommended. Cutting compounds of paraffin oil, such as are used in machining brass, are not satisfactory for aluminum.

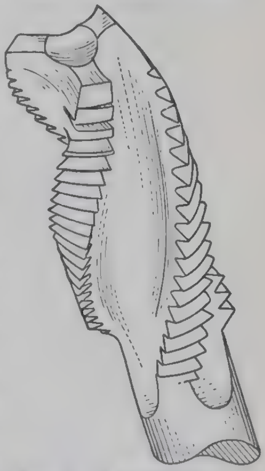

FIG. 7. Spiral fluted tap.

TOOL MATERIALS. Tools for machining aluminum may be either of high-carbon or high-speed steel. Cemented tungsten-carbide tools have been found indispensable, especially for machining aluminum alloys with high silicon content; they also are excellent for high production.

7. JOINING OF ALUMINUM

WELDING. Aluminum alloys may be joined by welding by the torch, electric arc, or resistance processes. In fusion welding, the equipment is the same as that used for welding steel, but in electrical resistance welding, machines of slightly different design and greater electrical capacity are required. The technique varies slightly from that required for steel. The metal arc generally will make stronger welds than can be made with the torch; however, $^3/_{32}$ in. is the practical minimum thickness of metal that can be so welded.

For metal arc electrodes and for torch welding filler rods for joining strong alloys, alloy 43S is most commonly used. A flux is used in fusion welding. In the metal arc process, the flux is best applied as a heavy coating on the electrode. When inert atmosphere is used, such as in argon, shielded-arc welding flux is not required.

Because of the effect of welding heat on the mechanical properties and resistance to corrosion not all the aluminum alloys are suitable for this method of joining. Wrought alloys 2S, 3S, 52S, 53S, 61S, and 63S find general application in components welded by gas or arc methods. Some use has been made of arc welding for 14S alloy. Resistance welding has been used for all the wrought and cast alloys. Arc welding has been employed for welding of all permanent-mold and sand-casting alloys except 220 and 750. Gas welding is applicable to some permanent-mold and sand-casting alloys such as 43, 195, B195, 214, 355, and 356. Die castings are normally neither gas nor arc welded.

SOLDERING. There are available a variety of solders and fluxes adapted to nearly all soldering requirements. The use of proper solder and flux enable aluminum alloy parts to be joined in much the same way and for about the same type of service as solder joints of other metals. Suitable directions can be obtained from the supplier of solder and flux. Of the wrought alloys, 2S, 3S, 53S, 61S, and 63S are used in soldered applications. All permanent-mold and sand-casting alloys can be soldered. Die castings are soldered by first copper plating and then using the usual methods employed for copper base alloys. The dissimilar metal in the soldered joint presents the possibility of electrolytic corrosion so that adequate protection is necessary for joints that may be exposed to corrosive conditions.

BRAZING. Aluminum alloys are brazed by furnace, torch, or dip methods. Not all the alloys can be brazed because of relationship of the melting points of the available brazing alloy and the various aluminum alloys. Of the wrought alloys, 2S, 3S, 53S, 61S, and 63S can be brazed. Of the permanent-mold and sand-casting alloys, 43, 355, 356, and 406 are brazed. Die-casting alloys are not brazed.

RIVETING. The joining of aluminum-alloy components by riveting is a common fabricating procedure. The particular alloy rivet selected depends on the strength requirement of the application. Table 12 lists typical shear strengths of the driven rivets for the alloys and condition of the aluminum-alloy rivets which have found most frequent application. When greater strength is required, zinc-coated steel rivets are sometimes used. It will be noted in Table 12 that properties are given for 17S and 24S alloys driven immediately after quenching (T31 temper). For most applications, particularly with rivets of larger size, it is not possible to do a satisfactory job of riveting with these alloys in the T4 condition, the alloy being too hard to drive without excessive cracking. It is common practice, therefore, with these alloys either to drive the rivets within 2 hours after solution heat treatment or as a convenient method to solution heat-treat the rivets and to store them at temperatures of 32 F or below until it is time to drive. By these methods the rivets are driven before precipitation hardening has progressed to such a degree as to make the rivets too hard for driving. At 32 F the solution heat-treated rivets can be maintained in a condition suitable for driving for periods up to about 36 hours. At lower temperatures, longer storing times are possible.

Table 12. Average Ultimate Shear Strengths of Driven Rivets *

Rivet	Driving Procedure	Shear Strength, psi
2S	Cold, as-received	11,000
A17S-T3	Cold, as-received	33,000
17S-T3	Cold, as-received	39,000
17S-T31	Cold, immediately after quenching	34,000 †
24S-T31	Cold, immediately after quenching	42,000 †
53S-T61	Cold, as-received	23,000
53S-T6	Cold, as-received	26,000
17S-T41	Hot, 930 to 950 F	33,000 †
53S-T41	Hot, 960 to 1050 F	18,000 †,‡
Steel	Hot, 1700 to 1900 F	45,000

* Values for rivets driven with cone-point heads. Rivets driven with heads requiring more pressure may be expected to develop slightly higher strengths.

† Immediately after driving, the shear strengths of these rivets is about 75% of the value shown. On standing at ordinary temperatures, they age-harden to develop their full strength, this action being completed in about four days for 17S and 24S rivets, and in about two weeks for 53S rivets.

‡ Shear strength for rivets driven at temperatures of 960 to 980 F. The shear strength increases about 1000 psi for each increase of 12 F in driving temperature.

Aluminum-alloy rivets are sometimes driven hot to facilitate driving. In order to obtain desirable strength and resistance to corrosion properties the rivets are heated to the solution heat-treatment temperature and driven. The contact of the hot rivet with the cold material around the rivet hole constitutes a sufficient quench to produce the desired properties.

In die casting, small studs are sometimes cast as an integral part of the casting. These studs are used instead of rivets in assembling the mating parts, the studs being pressed after assembly to form a "riveted" union.

Rivet holes may be either drilled, punched, subdrilled or subpunched, and reamed. The best clearance, which is the minimum that will permit expeditious insertion of the rivet in the hole, is usually about 2 or 3% of the rivet shank diameter. Hot riveting will require slightly greater clearance than cold riveting to facilitate insertion. Too great a clearance will result in poor upsetting during the driving operation. Taper bridge reamers of the spiral fluted type are recommended for reaming subdrilled or subpunched holes.

8. FINISHING OF ALUMINUM

FROSTED FINISH. This finish is used primarily for its appearance. It is common practice to anodize the "frosted" article to maintain the desired finish in service. Frosted finish usually is applied by etching in a hot solution of sodium hydroxide (caustic soda), followed by treatment with strong nitric acid to neutralize any remaining alkali and to remove any remaining smudge. For ordinary operations, the solution contains about 5% of caustic soda, although solution concentrations of 2 to 25% are sometimes used. The temperature of the solution is commonly kept at about 170 F. The time of immersion is determined by the temperature of the solution, its concentration, and the depth of etch desired. Usually treatments of about one minute are sufficient.

After removal from the caustic solution, the part is rinsed in clear water and immersed in a 1 to 1 nitric acid and water solution. Occasionally a weaker solution, for example, 10 to 15% nitric acid, is used.

MECHANICAL FINISHES. Aluminum alloys can be given a very pleasing variety of mechanical finishes by grinding, polishing, buffing, coloring, scratch brushing, hammering, fluting, sandblasting, and burnishing. These finishes can be applied in such a manner as to produce attractive designs on the article for decorative purposes or to produce a highly reflective or low reflective surface, as desired.

ELECTROPLATING. Aluminum may be electroplated with other metals to produce an attractive finish, to increase the wear resistance, to change the frictional characteristics, and for other more specialized purposes. A few examples of plating uses are: *silver* for increasing surface electrical conductivity; *brass* to facilitate vulcanization of rubber; *chromium* to increase wear resistance; *tin* to reduce friction; *copper* to permit soft soldering; and *zinc* for improving anti-seize characteristics of threaded parts.

Prior to electroplating, the part is given a pretreatment which provides adequate anchorage for the plated metal. The most commonly used method of pretreatment is the zinc immersion process, in which a chemically deposited zinc coating is applied. Anodizing and other etching methods are also used. After this pretreatment the desired metal is plated on in accordance with common plating procedures. Plating thickness will vary but should be sufficient to provide an impervious coating as a protection against undesirable galvanic action.

OXIDE COATINGS are one of the most important finishes for aluminum. These coatings are used to improve the corrosion resistance and appearance of the article and to provide a good base for subsequent paint coatings. In addition the anodic oxide coatings applied by the Alumilite process are sometimes used because of their hard abrasion-resistant characteristic. The anodic treatments consist of making the article to be coated the anode in a suitable electrolyte and passing the current necessary for producing the desired film characteristics. The conditions of coating will vary with alloy, electrolyte, and nature of coating desired. The coatings as produced are submicroscopically porous and range from a clear transparent film to one that is translucent or opaque, the color being governed by the alloy being coated and the process employed. The porous nature of the film is used to advantage in subsequent sealing treatments to cause corrosion inhibitors or dyes to be absorbed by the film. A great variety of colored oxide coatings can be produced which have desired eye appeal and resistance to corrosion. The characteristic of the oxide coating that reproduces the texture of the surface on which it is formed is made use of to preserve applied etches and mechanical finishes during service.

Oxide coatings are produced by chemical-treatment methods as well as by anodic oxidation. A series of patented chemical dip treatments, developed by the Aluminum Company of America and known as "Alrok" treatments, have found wide commercial use.

PAINTING AND LACQUERING. Aluminum may be coated with paint or lacquer by much the same technique as followed for other metals. Surface preparation is important. Frequently, all that is required is a cleansing from grease and dirt by wiping the surface with a cloth wet with mineral spirits or other solvent. Chromic acid solution and certain chemical cleansing agents, such as a phosphoric acid-alcohol mixture, sold under various trade names, give greatly improved paint adhesion. With castings, a light sand blast improves adhesion of paint. An anodic or chemical oxide coating provides exceptionally good adhesion, especially in painting for protection against salt-water corrosion.

A priming coat containing zinc chromate pigment is effective on aluminum. Aluminum paint is made by mixing aluminum powder or paste with a suitable vehicle. Aluminum paint, in the proportion of two pounds of powder to a gallon of vehicle, forms a coating of high moisture resistance and superior protective qualities. By proper choice of vehicle it can be used on metal, wood, plaster, or concrete and is particularly recommended for the painting of aluminum and its alloys.

Transparent varnishes or lacquers may be used to preserve polished surfaces. Many of them are sufficiently durable to be applied to exterior ornamental work. A varnish of light color and relatively insensitive to light exposure should be selected. Synthetic resins have increased durability, no clear finish, however, will last as long as pigmented finishes.

VITREOUS ENAMEL. Some application has been made of coatings of this type. Because of the relatively low melting point of aluminum alloys, however, the process is restricted to the use of a low temperature frit. They are generally of low resistance to corrosion and weathering.

9. ELECTRICAL USES OF ALUMINUM

Aluminum was first used as a conductor in high-tension wires in the United States in 1898. The first conductors were made entirely of aluminum. Later, however, a cable with an extra high strength steel reinforcing core for the aluminum strands was developed and has since been used with marked success.

CONDUCTIVITY. The AIEE standard of conductivity for hard-drawn aluminum wire is 60.97% of the International Annealed Copper Standard. On this scale the conductivity of commercial hard-drawn copper usually is taken at 97%.

The electrical conductivity of annealed high-purity (99.97%) aluminum is 64.6%, based on the International Annealed Copper Standard. The electrical conductivity is lowered by the addition of alloying elements, the reduction varying with the nature of the element and the amount added. Heat treatment and mechanical working also influence this property to a marked degree. The following are the approximate conductivities of various grades of aluminum and aluminum alloys:

Metal	99.97 Per Cent Al	Hard-drawn Conductors	2S-O	2S-H	3S-O	3S-H	14S-T	24S-T	61S-T
Conductivity, per cent of International Annealed Copper Standard	64.6	61	59	57	50	40	40	30	40

Conductivities of a number of other alloys are contained in AIMME, *Transactions of Metals Division*, Vol. 124, 1937, pp. 287–299.

CABLES AND CONDUCTORS. Aluminum cable, steel reinforced, is used for messenger cables of overhead catenary railway lines. In the smaller sizes, it also is used for signal circuits, and for telephone lines supported on the same structure with power lines, where its high strength permits the use of as long spans as the transmission conductors. Some spans as long as one mile have been used successfully. Because of its light weight, aluminum cable has made a welcomed contribution to the aircraft industry as an electrical conductor. It is also finding considerable application as building wire. Large all-aluminum cables have been used as railway feeders, where they carry heavy currents at relatively low voltages. Particularly in large conductors, the use of aluminum effects a great saving in weight. Conductors for high-voltage installations, such as outdoor substations, may advantageously be made of aluminum tubing. They are rigid and light, and permit the use of long spans which often are necessary to obtain electrical clearances, and show economy in supporting structures.

SWITCHBOARD CONSTRUCTION. Aluminum may be used to advantage in bus bar construction, both on switchboards and for general transmission of power. Aluminum bus bars are rolled and are available in the usual rectangular cross sections, as well as in channels and certain other structural shapes, which offer definite advantages in strength and current-carrying capacity. The current rating of aluminum bus bars may be conveniently taken as 84% of the accepted values for copper of equal cross section and similar shape.

ELECTRICAL MACHINERY. Aluminum is used for casting the rotor conductors of squirrel-cage induction motors and also for field windings in certain types of motors and high-speed turbo-generators.

COPPER AND COPPER-BASE ALLOYS

10. COPPER

By W. R. Hibbard *

COMPOSITION OF COMMERCIAL COPPER. Specifications for copper, generally accepted by industry, are the ASTM standard specifications. These cover lake copper, electrolytic copper, and fire-refined copper. Lake copper, which must originate on the upper peninsula of Michigan, may be low-resistance or high-resistance lake copper.

Low-resistance lake copper, used for electrical purposes, may be electrolytically or fire refined. It is required to have a content of (copper + silver) of not less than 99.900%. Maximum permissible resistivities in international ohms (meter, gram) are: copper wire bars, 0.15436; ingots and ingot bars, 0.15694.

High-resistance lake copper is lake copper of resistivity exceeding 0.15694 international ohm (meter, gram) at 20 C. Its (copper + silver + arsenic) content is not less than 99.900%.

Physical Properties of Copper

General Properties

Density	0.322 lb per cu in.	Specific heat at 77 F	0.0917
Melting point	1981 F	Electrical resistivity at 20 C	1.27 microhm-cm
Coefficient of expansion per °F	77–100 F 0.000 009 332 77–572 F 0.000 009 888	Temperature coefficient of resistivity at 20 C	0.0039 per °C
Pattern shrinkage	1/4 in. per ft.	Magnetic properties	Diamagnetic
Thermal conductivity at 77 F, Btu per hr per sq ft per in. thickness per °F	2679	Optical properties	Selectively reflecting
		Young's modulus	17,300,000

Tensile Properties

	Annealed	Cold Rolled or Drawn	Cast
Tensile strength, psi	30,000 40,000	50,000–70,000	20,000 30,000
Elongation in 2 in.	40–60%	2–4%	25–45%
Reduction of area	40–60%	2–4%	....

Hardness

	Annealed	Cold Rolled or Drawn
Brinell (500 kg)	30–40	60–100
Scleroscope (Universal Hammer)	6–8	20– 25

Electrolytic copper specifications for purity and resistivity are the same as those of low-resistance lake copper.

Fire-refined copper, other than lake, is used for rolling into sheets and shapes. It is not acceptable for electrical uses. ASTM Specification B216-47T, Fire-refined Copper for Wrought Products and Alloys, calls for the following analysis: Cu + Ag, min, 99.88%; As, max, 0.012%; Sb, max, 0.003%; Se + Te, max, 0.025%; Ni, max, 0.05%; Bi, max, 0.003%; Pb, max, 0.004%.

Oxygen-free high-conductivity copper is a highly ductile material, made under conditions that prevent the entrance of oxygen and formation of copper oxide. It is utilized in deep-drawing, spinning, and edge-bending operations, and in welding, brazing, and other hot-working operations where embrittlement must be avoided. It has the same conductivity and tensile properties as touch pitch electrolytic copper.

HARDENED COPPER. There are only two methods for hardening copper: by cold working it or by alloying with it small amounts of other elements such as silicon, tin, zinc, and aluminum. Both these methods are in commercial use. When copper is hardened with tin, silicon, or aluminum it generally is called bronze; when hardened with zinc, brass.

CORROSION. Copper is resistant to the action of sea water, and to atmospheric corrosion. It is not resistant to the common acids, and is unsatisfactory in service with ammonia and with most compounds of sulfur. Manufacturers should be consulted in regard to its use under corrosive conditions.

FABRICATION. Copper may be hot or cold forged, hot or cold rolled, hot extruded, hot pierced, and drawn, stamped, or spun cold. It can be silver-soldered, brazed, and welded. For welding by the oxyacetylene torch or electric arc, the oxidized copper will give more satisfactory welds than electrolytic or lake copper. Copper cannot be cut by the oxygen jet because of its high heat conductivity. Copper is annealed from 480 to 1400 F, depending on the properties desired, and in a slightly oxidizing atmosphere. Ordinary commercial annealing is done in the neighborhood of 1100 F. A reducing atmosphere will make the copper brittle and unfit for use. Copper may be electrodeposited from the alkaline cyanide solution, or from the acid sulfate solution.

---

* Revision of material originally prepared by the late W. H. Bassett.

STANDARDS. The following is a list of the specifications for copper for various purposes given in the 1947 ASTM Standards:

Designation B4-42, Lake Copper Wire Bars, Cakes, Slabs, Billets, Ingots, and Ingot Bars; B5-43, Electrolytic Copper Wire Bars, Cakes, Slabs, Billets, Ingots, and Ingot Bars; B72-47T, Fire-refined Casting Copper; B1-47, Hard-drawn Copper Wire; B2-47, Medium Hard-drawn Copper Wire; B3-45, Soft or Annealed Copper Wire; B33-46, Tinned Soft or Annealed Copper Wire for Electrical Purposes; B8-48, Concentric-lay-stranded Copper Conductors, Hard, Medium-hard, or soft; B11-47, Copper Plates for Locomotive Fireboxes; B12-47, Copper Rods for Locomotive Staybolts; B13-41, Seamless Copper Boiler Tubes; B42-47, Copper Pipe, Standard Sizes; B47-46, Copper Trolley Wire; B48-48T, Soft Rectangular and Square Bar Copper Wire for Electrical Conductors; B49-41, Hot-rolled Copper Rods for Electrical Purposes; B68-47, Seamless Copper Tubing, Bright Annealed; B75-48T, Seamless Copper Tubes; B88-48, Copper Water Tube; B116-46, Figure-9 Deep-section Grooved and Figure-8 Copper Trolley Wire for Industrial Haulage; B133-48T, Copper Rods, Bars and Shapes; B152-48T, Copper Sheet, Strip and Plate; B170-47, Oxygen-free Electrolytic Copper Wire Bars, Billets, and Cakes; B172-44T, Rope-lay-stranded Copper Conductors Having Bunch-stranded Members for Electrical Conductors; B173-47T, Rope-lay-stranded Copper Conductors Having Concentric-stranded Members for Electrical Conductors; B174-45T, Bunch-stranded Copper Conductors for Electrical Conductors; B187-48T, Copper Bus Bars, Rods, and Shapes; B188-47T, Copper Bus Pipes and Tubes; B189-48, Lead-coated and Lead-alloy-coated Soft Copper Wire for Electrical Purposes; B216-47T, Fire-refined Copper for Wrought Products and Alloys.

11. SAND-CAST COPPER-BASE ALLOYS

By Carter S. Cole *

The principal standard alloys used by engineers and architects in the form of sand castings of various copper-base alloys are given in Tables 1 and 2. A cross index of the approximately equivalent specifications for the various alloys is given in Table 3. Information on high-conductivity castings and other special alloys, such as high-tin bronzes and gear bronzes, is given later in this article.

SELECTION OF ALLOY. Table 1 is an outline of the various types of alloys generally used for certain purposes. In selecting a specific alloy for a given use the foundry should be consulted, and it should always be borne in mind that experience in the same or similar applications is the best criterion for selection. This is particularly important when corrosion resistance, or some other special property, is required. All the copper-base alloys are generally resistant to corrosion, but for specific environments, especially chemicals, the manufacturer of the alloy should be consulted as to its use under the proposed conditions, or tests made on samples to prove suitability.

The relative value of these alloys for mechanical purposes varies with temperature, and information on this point should be obtained before subjecting them to high-temperature service.

DESIGN OF CASTINGS. (See Section 19, Article 15.)

SPECIFICATION AND INSPECTION. (See Section 19, Article 16.)

FABRICATION. Nearly all the sand-cast copper-base alloys listed are readily machined. Those containing lead fall especially in this category. Some of the stronger alloys, such as aluminum-bronze and manganese-bronze, are tough and difficult to machine, but with proper tool angles and machine conditions they can be handled. The silicon-bronze, aluminum-bronze, and manganese-bronze alloys are the more readily weldable, but those containing lead do not lend themselves to welding technique. It should be noted that, for each of the alloys listed in the group of high-tensile brasses and bronzes in Table 2, a number of variants other than the "nominal" compositions shown in Table 2 conform to the specification requirements for these alloys shown in Table 3.

PHYSICAL PROPERTIES. The physical properties of the more important standard alloys are given in Table 2, along with remarks regarding the general characteristics of each alloy and typical reported uses. Alloy number designations used in this and the other tables are the standard designations for the alloys adopted by the American Society for Testing Materials and the Brass and Bronze Ingot Institute (formerly the Non-ferrous Ingot Metal Institute) from whose Handbook most of the data given in Table 2 have been taken. The rest of the data given in Table 2 are taken from other sources deemed reliable. Attainment of the properties indicated is, of course, dependent on proper foundry technique, proper melting, pouring, gating, venting, and feeding as well as conformance to the requirements of the specifications for the alloys shown in Table 3.

Pump bodies	Bronze and red brass	2A-4A
Pumps		
Lubricating oil	Yellow brass	6B
Water	Red brass and semi-red brass	4A-5A-5B
Radiator valves	Red brass	4A
Resistance to wear	Aluminum-bronze	9A-9B-9C
Resistance to corrosion	*See* Corrosion resistance	
Resistance to shock	Aluminum-bronze	9A-9B
Severe duty	Bronze	1B-2A
Steam fittings	Bronze or red brass	2A-4A
Steam metal	Bronze	2A
Strength	Aluminum-bronze	9A-9B-9C
	Manganese-bronze	8A-8C
	Naval brass	6C
Structural parts	Manganese-bronze	8A-8C
	Silicon bronze and brass	12A-13B
Toughness	Aluminum-bronze	9A-9B-9C
	Manganese-bronze	8A
Under-water fittings	Manganese-bronze	8A
Valve bodies		
Chemical	Aluminum-bronze	9A-9B
High-pressure	Bronze	1B
Valve stems	Manganese-bronze	7A
Valves	Bronze	1B-2B
	Red brass	2A-4A
Low-pressure	Red brass	4A
Radiator	Red brass	4A
Water Fittings	Red brass and semi-red brass	4A-5A-5B
Water tightness	Bronze	2A-4A
Wear resistance	Aluminum-bronze	9A-9B
Worm wheels	Aluminum-bronze	9A-9B
	Manganese-bronze	8A

SPECIAL ALLOYS. There are a number of other recognized standard alloys and many alloys used for special purposes that have not been listed in Table 2. They were omitted primarily because they are of relatively low tonnage use and also because, for most of the special-purpose alloys, standardization of specifications has not advanced as far as it has for the alloys listed in Tables 2 and 3. Among the more important of such special uses of cast copper-base alloys are the following.

High-conductivity castings.* Although it is possible to cast unalloyed copper, the foundry problems are such that many special deoxidants are used. Consequently, such castings have a conductivity of about 80 to 85%. The term *high conductivity* is, however, variously applied to castings with a conductivity in excess of 30%.

One of the commonly used alloys in this class contains 0.80% chromium and 0.08% silicon. This alloy is heat treatable, and a conductivity of 85%, a yield strength of 35,000 psi, a tensile of 52,000 psi, and an elongation in 2 in. of 13% can be attained. Another silicide precipitation alloy with 2.5% nickel and 0.60% silicon can be produced with a conductivity of 45%, a yield strength of 65,000 psi, a tensile strength of 75,000 psi, and a Brinell hardness of 140.

(Continued on p. 4-29)

Note 1. Although the specifications for the several alloys as listed in this table are approximately equivalent in most of the essential details, there are some requirements that may differ. Therefore, if material is ordered to any one of these specifications, that particular specification should be consulted.

ASTM specifications may be obtained from the American Society for Testing Materials, 1916 Race St., Philadelphia, 3, Pa. Federal specifications may be obtained from the Superintendent of Documents, Washington, 25, D.C. Navy specifications may be obtained from the Bureau of Supplies and Accounts, Navy Department, Washington, 25, D.C. SAE specifications may be obtained from the Society of Automotive Engineers, 29 West 39th St., New York, 18, N.Y.

Note 2. Federal Specifications: FF-H-106, FF-H-111, FF-H-116b, FF-H-121a, FF-H-136, and WW-P-541a.

Beryllium-copper castings with about 2.0% beryllium, 0.50% cobalt plus iron, and 0.25% silicon have a minimum tensile of 78,000 psi and an elongation in 2 in. of 29% in the "as cast" condition and, when heat-treated, 155,000 psi tensile with 2% minimum elongation. This alloy has a Rockwell hardness of B76 as cast, and C35 when heat treated. Conductivities of some 50 to 65% can be realized.

There are also "conductivity" castings with over 90% copper made by using small amounts of tin and zinc—just sufficient to give good casting properties. However, none of these conductivity alloys is as yet covered by commercial specifications (except for the Navy Specification 46C11a for beryllium copper).

Bell Metal. The now obsolete Navy Specification 23B2 called for 78% copper, 22% tin. (The revised Navy Specification for Bells—23B2a—called for a silicon-bronze alloy.) Commercial bells are made with an 81-19 copper-tin alloy, or even lower tin.

Bridge Bearing Plates. Generally high tin bronzes are used. [See ASTM Specification B22—Class A (19% tin); Class B (16% tin)—both 1.0 maximum phosphorus.] The 80-10-10 alloy and 88-10-2 are also used where bearing loads are lighter.

Piston Rings. High tin bronzes similar to B22, Classes A and B, are generally used. May be centrifugally cast.

Rolling Mill Screw Down and Stripper Nuts. High tin bronzes of about 16% tin deoxidized with phosphorus are generally used with a Brinell hardness (500-kg load) of 83 to 93.

Gear Bronzes. High tin alloys—usually with about 11% tin (see SAE 65)—are quite generally used. One% or more nickel is often added and sometimes 0.5 to 1.5% lead. (See, for example, SAE 640.)

For all these special applications it is especially advisable that the foundry be consulted so that the most suitable alloy for the purpose in hand will be chosen.

12. WROUGHT COPPER-BASE ALLOYS

By W. R. Hibbard *

The nomenclature used in the nonferrous metals trade is confusing to those who are not familiar with the business, but through long usage it has become so thoroughly rooted that it is practically impossible to change it. The trade names have an actual value to the producers of various materials, and they would, therefore, naturally resist changes.

All questions of properties of engineering material are tied up with factors of safety, factors of reliability, conditions of exposure (which are always local), and similar matters. The requirements of special alloys for specific purposes may be considered from the viewpoint of the physical requirements or resistance to corrosion or both. The physical requirements and properties may be studied in the laboratory. The question of corrosion is less easily solved, because of the difficulty of reproducing in the laboratory the conditions to which the metal may be exposed in service.

(*Continued on p. 4-40*)

* R = Rod. S = Sheet. T = Tube. W = Wire. P = Plate.

† For some alloys the figures are for a temper slightly different from that commonly known as "hard."

[a] Determination.

[b] Elongation of wire in 10 in., %.

[c] Yield point taken as the load producing an extension under stress of 0.50%.

[d] At 18.1 C.

[e] Cold worked and heat treated.

[f] Annealed, quenched, and heat treated.

[g] Btu per sq ft per hr per 1 in. thick per 1° F, at 68 F.

The joint use of "dissimilar" alloys has caused much trouble. For instance, the use of one of the so-called stronger brasses (one of the brasses sometimes called bronzes which contains a considerable percentage of zinc together with tin or iron or a combination of these elements) in connection with a straight copper-tin bronze in an electrolyte such as sea water will result in the weakening of the alloy containing the larger proportion of zinc. Where brass strainers have been held in position with copper or gun-metal bolts and where brass screens have been placed in position with copper rivets, galvanic action has occurred, destroying the alloy containing the greater percentage of zinc.

Before proceeding with design, engineers not thoroughly familiar with the composition and properties of the alloys with which they propose to deal should consult reputable metallurgists, giving a thorough review of the conditions under which the material is to be used. The question of conditions of use is very important and should be carefully considered.

The so-called season cracking of brasses and bronzes has given much trouble in certain places. This phenomenon is due to the internal stress in the alloy brought about by cold working, such as rolling and drawing, and corrosive action. Copper and the copper-zinc alloys containing 20% or less of zinc are seldom subject to this trouble. The stronger copper-zinc alloys, as well as those containing tin and other elements, may be prepared so as to prevent this difficulty if the conditions of exposure are understood beforehand.

Table 4 gives an idea of what may be expected in the way of physical properties from some of the more common combinations of metals, but should be used as a general guide only. Table 5 is an index to the alloys of Table 4. Table 6 lists the ASTM specifications covering the alloys listed in Table 4.

Table 4 gives the more common wrought alloys with their ordinary physical properties, both "hard rolled" or "drawn" and "annealed" or "soft." The figures are averages that ordinarily may be expected in practice but may be modified by "extra hard," "half hard," or "quarter hard" rolling. In other words, almost any physical properties between the figures for "hard" and "soft" may be obtained by appropriate working, and higher figures for tensile strength, or hardness, may be obtained by a greater amount of working. The alloys have been chosen to represent the more commonly used copper-zinc, copper-zinc-nickel, copper-tin, and copper-aluminum mixtures. The alloys intermediate in composition between those chosen have physical properties lying between those given for the nearest compositions.

MAGNESIUM AND ITS ALLOYS

By William H. Gross

Magnesium, with a specific gravity of only 1.74, is the lightest metal available for engineering use. Chief source is sea water which contains about 0.13% magnesium. It is first mixed with lime produced by the roasting of oyster shells. Calcium in the lime replaces magnesium in the sea water, producing magnesium hydroxide, which is treated with hydrochloric acid prepared from natural gas and chlorine. Magnesium chloride produced by this reaction is electrolytically converted to metallic magnesium and chlorine gas, the magnesium being cast into pigs.

13. PROPERTIES AND AVAILABILITY

Like other pure metals, magnesium must be alloyed to give maximum strength and usefulness. Although lightness is its outstanding characteristic, it has other properties that are equally significant. Magnesium is extremely easy to machine and is adaptable to practically all the usual methods of metal working. It can be joined by gas, arc, and electric resistance welding and by riveting. Other significant properties include good stability to atmospheric exposure and resistance to attack by alkalies, chromic and hydrofluoric acids, and many organic chemicals such as hydrocarbons, aldehydes, alcohols, phenols, amines, esters, and most oils. The alloys of magnesium have relatively low electrical resistivity and high thermal conductivity. Magnesium is nontoxic and nonmagnetic.

The common commercial alloys of magnesium are listed in Table 1 under the designations of the ASTM and of the two largest producers of alloy ingot. Physical constants are given in Table 2.

AVAILABILITY. Pure magnesium is furnished in ingot for remelting and in the form of extruded sticks for alloying with other metals or for chemical uses. The alloys are produced in the form of ingots or billets; as sand, permanent mold, and die castings; forgings; extruded bars, round rods, tubing, and solid shapes; and as rolled sheets, strip, and plate.

CASTINGS. **Sand castings of magnesium** find widespread use in aircraft engines and aircraft landing wheels where light weight, high strength, and shock resistance are of prime importance. In high-speed rotating and reciprocating parts, their light weight is used to effect smoother operation and to reduce starting inertia. The printing and textile industries offer many examples of such uses. Portable tools and manually handled equipment of all kinds, such as vacuum cleaners, portable grinders, polishers, and foundry flasks have always presented a large market for cast-magnesium alloys. The excellent machining characteristics of magnesium sand castings provide reason for using magnesium in some instances.

Modulus of elasticity, 6,500,000 psi. Modulus of rigidity, 2,400,000 psi. Poisson's ratio, 0.35.

Permanent-mold castings, in addition, have closer tolerances on dimensions, better finish, and require less machining. Magnesium alloy permanent mold castings are being used for such parts as nose pieces on aircraft engines, fittings, wheel flanges, pistons, brackets, and various types of housings.

Die castings possess such advantages as extremely accurate dimensions, reduction of machining, excellent surface finish, and low cost. These characteristics have caused magnesium die castings to be widely used in such applications as small aircraft engine parts, instrument parts, various kinds of housings, aircraft landing wheels, vacuum cleaner parts, miscellaneous boxes and covers, and innumerable other parts where light weight is essential.

Table 3 lists typical mechanical properties of magnesium castings. Sand and permanent-mold castings have essentially the same properties, and some of the alloys are used interchangeably for castings of these types. Only one alloy composition is in common use for die casting. This alloy is sometimes sand cast for special purposes.

* Yield strength is defined as the stress at which the stress-strain curve deviates 0.2% from the modulus line.

FORGINGS. Magnesium forgings, combining good strength, light weight, and pressure tightness, are suited for a wide variety of applications. Typical uses for alloy forgings include aircraft engine bearing caps, rocker-arm supports, door and aileron hinges, engine mountings, cylinder heads, valve and pump bodies, hydraulic cylinders, supercharger parts, horn disks, miscellaneous control levers, brackets, fittings, and similar applications. Table 4 contains the typical mechanical properties of magnesium forgings.

Table 4. Typical Mechanical Properties of Magnesium Forgings

* Yield strength is defined as the stress at which the stress-strain curve deviates 0.2% from the modulus line.

† Properties for M1 alloy are based on both press and hammer forgings; those for AZ61 and AZ80 are for press forgings only.

EXTRUSIONS. Magnesium extrusions have been used extensively in the aircraft, textile, and transportation industries, and in portable equipment. Other specific uses of magnesium extrusions include such applications as floor beams, moldings, stiffener elements in aircraft structures, the framework of bus and airplane seats, bus and trailer body frames, and structural members in a wide variety of parts. In Table 5 are given the typical mechanical properties of extruded magnesium rods and bars, tubes, and solid shapes.

SHEET AND PLATE. Magnesium sheet can be arc, gas, and spot welded; formed; drawn; spun; and riveted. Magnesium sheet and plate have been used in such parts as aircraft wings, wing tips, ailerons, fairings, oil and fuel tanks, cases, floor plates, ducts, conveyors, seats, venetian blinds, bus and trailer bodies, and dock boards. Typical mechanical properties of magnesium sheet and plate are listed in Table 6.

NONSTRUCTURAL USES. The fields of usefulness for magnesium alloys can be divided into two types, chemical and structural. Chemical uses include magnesium as an

† The properties for bars and rods apply to sizes $1/4$ to $1\ 1/2$ in. in diameter or $2\ 1/2$ sq in.

alloying element in aluminum and zinc alloys. Other nonferrous alloys also utilize magnesium as an alloying ingredient although to a lesser extent. Magnesium is also used metallurgically as an oxygen scavenger or deoxidizer in the manufacture of copper and nickel alloys. One of the best-known nonstructural applications for magnesium is as a catalyst in the well-known Grignard reaction of organic chemistry. When alloyed with 30% or more of aluminum and ground into a powder, magnesium finds use in pyrotechnics. The magnesium anode is used for the cathodic protection of other metals from corrosion.

Table 6. Typical Mechanical Properties of Magnesium Plate, Sheet, and Strip

Alloy	Condition	Tension			Compression	Shear	Hardness	
		Tensile Strength, psi	Yield Strength,* psi	Elongation in in., %	Yield Strength,* psi	Ultimate Stress, psi	Brinell, 500-kg load, 10-mm ball	Rockwell E

M1	Hard rolled	37,000	29,000	8	20,000	17,000	56	67

* Yield strength is defined as the stress at which the stress-strain curve deviates 0.2% from the modulus line.

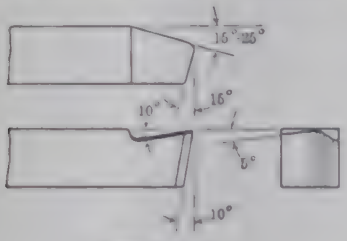
Successful protection has been provided on underground metal structures like oil, brine, and gas lines, well casings, telephone and telegraph cables, and buried tanks. In order to protect such structures it is necessary only to bury magnesium anodes in the ground at intervals adjacent to the structure to be protected and then connect the two by means of a wire.

14. MACHINING OF MAGNESIUM ALLOYS

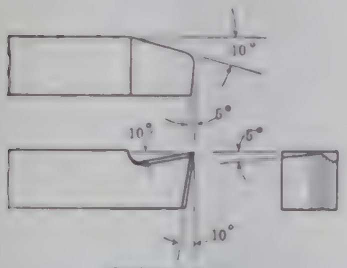
Magnesium can be worked by practically all methods known to the metal-working art, using the same tools employed on other metals. In some of these operations magnesium exhibits a pronounced superiority to other metals in common use. Particularly outstanding is its machinability.

High-speed steels are recommended as cutting-tool materials although carbide-tipped tools produce worthwhile economies on high-production jobs. Oil-type coolants are quite generally used, particularly for parts which must be held to close dimensions, on small parts, or when taking fine cuts. When a coolant is indicated, only oil type—never water-soluble oils or emulsions—should be used. This is important because magnesium chips cannot be easily ignited when generously wetted with oil. On the other hand, damp chips can be ignited by a chance spark.

TURNING, BORING. Figure 1 shows recommended angles for grinding single-point tools for rough turning and finishing operations on magnesium. Angles conform to the terminology advocated by the American Standards Association. Table 7 gives feeds, speeds, and position of cut for turning and boring magnesium.



Roughing tool



Finishing tool

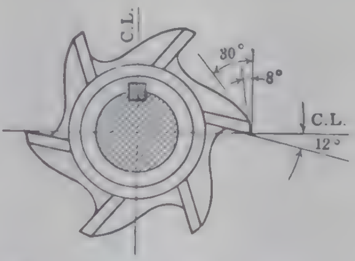

FIG. 2. Milling cutter suitable for magnesium alloys.

Table 7. Recommended Speeds, Feeds, and Depths of Cut for Turning and Boring Magnesium

Operation	Speed, ft per min	Feed, in. per revolution	Maximum Depth of Cut, in.
Roughing	300 to 600	0.030 to 0.100	0.500
	600 to 1000	0.020 to 0.080	0.400
	1000 to 1500	0.010 to 0.060	0.300
	1500 to 2000	0.010 to 0.040	0.200
	2000 to 5000	0.010 to 0.030	0.150
Finishing	300 to 600	0.005 to 0.025	0.100
	600 to 1000	0.005 to 0.020	0.080
	1000 to 1500	0.003 to 0.015	0.050
	1500 to 2000	0.003 to 0.015	0.050
	2000 to 5000	0.003 to 0.015	0.050

MILLING. Coarse-toothed milling cutters having one-half to one-third as many teeth as cutters commonly used on steel are best for magnesium. Figure 2 shows proper tool angles; Table 8 gives recommended operating details.

Table 8. Recommended Speeds, Feeds, and Depths of Cut for Milling Magnesium

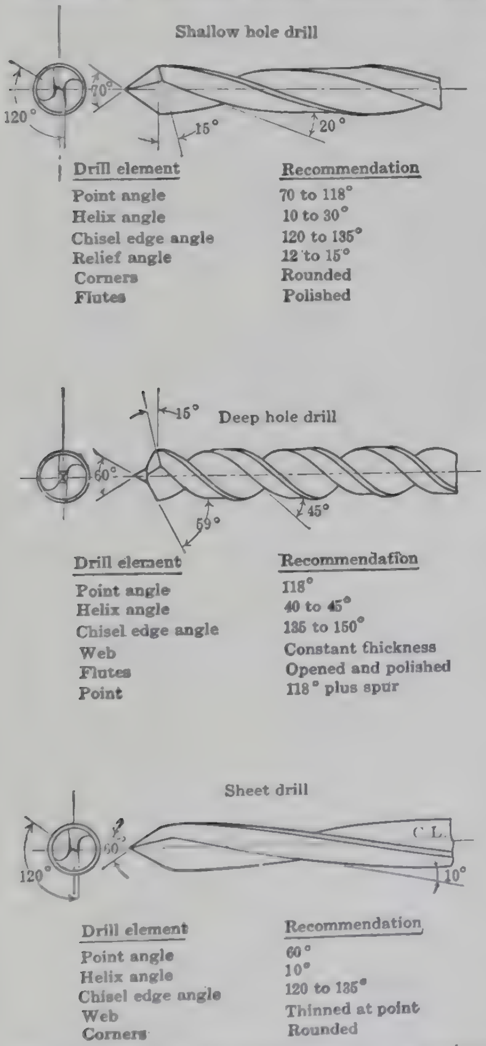
Operation	Speed, ft per min	Feed		Depth of Cut, in.
		in./min	in./tooth	
Roughing	Up to 900	10 to 50	0.005 to 0.025	Up to 0.500
	900 to 1500	10 to 60	0.005 to 0.020	Up to 0.375
	1500 to 3000	15 to 75	0.005 to 0.010	Up to 0.200
Finishing	Up to 900	10 to 50	0.005 to 0.015	Up to 0.075
	1000 to 3000	10 to 70	0.004 to 0.008	0.005 to 0.050
	3000 to 5000	10 to 90	0.003 to 0.006	0.003 to 0.030
	5000 to 9000	10 to 120	0.002 to 0.005	0.003 to 0.030

DRILLING. Three types of drills (see Fig. 3) are in use for the various types of drilling requirements normally included in machine-shop work. They include a drill for deep holes, one for shallow holes, and a low-helix-angle drill recommended to prevent the work from "walking" up the drill when drilling thin sheet. Table 9 gives recommended drilling data. Reamers, like milling cutters, should have fewer flutes than usual. Typical reamer for use on magnesium is shown in Fig. 4.

Table 9. Recommended Speeds and Feeds for Drilling Magnesium

Drill Diameter, in.	Speed, ft per min	Feed, in. per revolution		
		Sheet	Shallow Holes	Deep Holes
1/4	300 to 2000	0.005 to 0.030	0.004 to 0.030	0.004 to 0.008
1/2	300 to 2000	0.010 to 0.030	0.015 to 0.040	0.012 to 0.020
1	300 to 2000	0.010 to 0.030	0.020 to 0.050	0.015 to 0.030

TAPPING. Ground-thread high-speed steel taps are advocated for magnesium.



Drill element	Recommendation
Point angle	70 to 118°
Helix angle	10 to 30°
Chisel edge angle	120 to 135°
Relief angle	12 to 15°
Corners	Rounded
Flutes	Polished

Drill element	Recommendation
Point angle	118°
Helix angle	40 to 45°
Chisel edge angle	135 to 150°
Web	Constant thickness
Flutes	Opened and polished
Point	118° plus spur

Drill element	Recommendation
Point angle	60°
Helix angle	10°
Chisel edge angle	120 to 135°
Web	Thinned at point
Corners	Rounded

FIG. 3. Three types of drills used on magnesium alloys.

SAWING AND FILING. Saws for use on magnesium should have fewer teeth than usual to take care of the extra dust produced by the heavier feeds of operation which the easy machinability of magnesium makes possible. By the same token the best files for use on magnesium are single and double cut of the coarse bastard and single-cut types. Hardened, high-speed steel rotary files and burrs are best for power-operated filing operations.

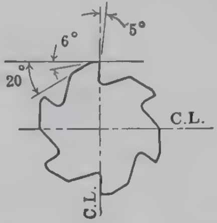


FIG. 4. Reamer for use on magnesium alloys.

Sludge

FIG. 5. Diagram of dust collection system considered safe for use with magnesium.

HANDLING. Good housekeeping is the answer to safe handling of magnesium in finely divided form. Heavy pieces of solid magnesium are extremely difficult to ignite since the material must be heated to about its melting point. Fines, particularly if moistened with water, might be ignited by a stray spark. For this reason chips, turnings, saw dust, and similar fines should be swept up frequently and placed in a covered metal container. If a magnesium fire should occur on a machine tool it can be extinguished with dry graphite powder or cast-iron borings. Liquid or gas-type fire extinguishers or water should not be used on such fires. Proper dust-collection equipment should be used on grinding. A safe unit is one in which dust is immediately drenched with water as soon as it leaves the grinding wheel. A diagram of a safe set-up is shown in Fig. 5. It has been found very desirable to have the power connected in such a way that the grinder, air blower, and water circulation will operate simultaneously.

15. JOINING OF MAGNESIUM ALLOYS

Magnesium structures can be joined by a number of the common methods, including riveting, arc welding, gas welding, spot welding, and, of course, by bolts and screws.

RIVETING. Aluminum-alloy rivets are universally used in magnesium joints. Aluminum 56S rivet alloy is recommended because of the minimum danger of galvanic corrosion. 17S and 24S compositions have good strength but should not be used for joints which will be exposed to the weather or corrosive atmosphere. 2S aluminum rivets are easy to drive and give a minimum of trouble from galvanic corrosion, but their use is limited to lightly stressed joints. Choice of rivet diameter is important and is governed by proper balance between the shear strength of the rivet and the bearing strength of the sheet. With 56S rivets in the quarter-hard condition (1/4 H), a good rule is to use a rivet diameter approximately three times the sheet thickness. The distance from the center line of the first row of rivets in a joint to the edge of the sheet, defined as "edge distance," should not be less than 2 1/2 times the rivet diameter. Spacing between rivets should be not less than three times the rivet diameter. Pneumatic hammers can be used for driving rivets into magnesium joints although hydraulic squeeze rivets are preferred when they can be used. Although 56S aluminum rivets are usually driven cold in the quarter-hard condition (1/4 H), rivets with diameters of 5/16 in. and greater are often heated to 650 F immediately before driving.

ARC WELDING of magnesium is done with a special torch equipped with a small cup surrounding the electrode through which an inert gas such as argon or helium flows during welding. The inert gas forms a blanket over the molten metal and prevents oxidation. This eliminates the need for a flux, which is required in gas welding. Either direct current with reversed polarity or alternating current with superimposed high frequency is used in the arc-welding process. Magnesium welding rod of approximately the same composition as the metal being welded is used during arc welding. Table 10 gives machine settings and other recommendations for arc-welding magnesium. The flow of inert gas is given in cubic feet per minute, and it is possible to obtain meters that will read directly in argon or helium flow in cubic feet per minute.

Table 10. Recommendations for Welding Magnesium with Helium or Argon Shielded Arc

MACHINE WELDS (One Pass Each Side on Square Edges)							
3/8	300	HF a-c 3/16	..	.31	...	1/4	3/4
1/2	375	HF a-c 3/16	..	.31	...	1/4	3/4

* Currents shown are for all alloys except ASTM alloy M1, which requires 5 to 10 amp more current for material up to 0.050 in. and 15 to 30 amp more current for thicker material. Currents given are for welding speeds of 12 in. per min.

† Sheet thicker than 0.150 in. should be welded in more than one pass. A current of about 60 amp is used on the first pass, and the currents given in the table are used for subsequent passes.

GAS WELDING. Oxyacetylene, oxyhydrogen, and oxycarbohydrogen flames can be used for gas-welding magnesium. Oxycarbohydrogen is recommended in preference to the other two. It provides a cooler flame than oxyacetylene and a more easily seen and, therefore, a more easily adjusted flame than the oxyhydrogen. A flux must be used when gas-welding magnesium, and for this reason gas welds are limited to butt joints and to single-pass welds. Flux entrapped in the joint can result in corrosion difficulties later because the flux is hygroscopic and will take on moisture. Normally the filler rod is of the same composition as the material being welded. Fluxes are prepared for use by mixing two parts of the dry powder with one part of water, forming a paste which should be brushed onto both edges of the joint and on the rod. The choice of rod size and other necessary operating information is given in Table 11 for oxycarbohydrogen and oxyacetylene flames. Immediately after welding, the bead should be scrubbed with a stiff brush dipped in hot water. Next the part should be dipped for one minute in a solution containing 1 1/2 lb sodium dichromate and 1 1/2 pints of concentrated nitric acid, and water to make a total of one gallon. This is the same solution used for applying the chrome-pickle treatment to provide a paint base on magnesium, described later. After one minute in this solution the welded part should be washed in running water and then boiled for 2 hours in a solution containing 1/2 lb of sodium dichromate and 1 gal of water. Upon removal from this solution the welded part should be rinsed thoroughly in cold running water and then dipped in hot water to facilitate drying.

Table 11. Recommendations for Gas-welding Magnesium

OXYACETYLENE

STRESS RELIEF OF ARC AND GAS-WELDED JOINTS. Both arc and gas welding of magnesium set up residual stresses in the metal which must be relieved by suitable treatment. Table 12 gives times and temperatures for various alloys in cast and wrought forms.

Table 12. Recommended Stress-relieving Times and Temperatures for Magnesium Alloys

Magnesium Alloy	Form	Stress-relieving Treatment	
		Time	Temperature, °F
M1h *	Hard-rolled sheet	1 hour	400
AZ31h	Hard-rolled sheet	1 hour	275
AZ51h	Hard-rolled sheet	1 hour	375
A11	Annealed sheet and extrusions	15 min	500
A11	Sand castings	1 hour	500

* Alloy M1 is not subject to stress corrosion cracking but stress relief of welded joints may be desirable to prevent distortion during machining.

SPOT WELDING. Electric resistance spot welding is an excellent method of joining wrought magnesium. Both d-c and a-c welding machines are satisfactory. Welding electrodes should have dome tips made from a hard copper alloy with high electrical conductivity. Actual machine settings can be obtained from a magnesium manufacturer, but to those already familiar with spot-welding procedures on other metals it may suffice to say that machine settings will be very similar to those used for aluminum. Before welding is begun, contacting surfaces should be thoroughly cleaned with a solvent to remove oil and grease. Next, the surface should be polished to a bright luster with a wire brush or steel wool. Stainless steel wire brushes and steel wool are recommended because stainless steel is not magnetic and, therefore, particles will not be attracted to the welding area to contaminate the surface. Electrode tips should be kept clean during welding by polishing with an emery cloth. Some alloys require that the electrode tips be cleaned after every ten or fifteen welds. This is true of pure magnesium and alloy M1. With other alloys, such as alloy AZ51, as many as one hundred and fifty welds can be made between cleanings.

16. FORMING OF MAGNESIUM ALLOYS

Most of the common methods used for converting metal sheet and extrusions into useful shapes are applicable to magnesium. Deep drawing, shallow drawing, pressing, stretch forming, spinning, and similar processes are in regular commercial use.

PRESS DRAWING is done on both hydraulic and mechanical presses although hydraulic presses usually are preferred because of better control of drawing speed. Most forming is done hot, which has advantages over cold working of magnesium. Because of its crystalline structure, the working of magnesium at elevated temperatures puts more planes of slip into play, and many intricate parts can be drawn in one operation without intermediate annealing steps and with only one set of dies being necessary. Hot working likewise results in parts made to exact size with no "spring back" when the finished piece is removed from the die. An entering radius on the draw ring five to seven times the sheet thickness gives maximum draw ability. The male die or punch is usually heated by means of gas burners or electric strip heaters inside the punch. The draw ring is also heated. Care should be taken when using a gas flame that it impinges only on the surface to be heated and not on the magnesium sheet. The magnesium sheet is usually preheated in an oven prior to forming. Shallow parts, flanges, and similar shapes not requiring deep drawing action can be rubber formed by the Guerin process of rubber forming.

DROP FORMING. The drop hammer has been successfully used as a means of forming magnesium sheet. Zinc alloys are satisfactory for drop hammer dies when the temperatures do not exceed 500 F. Lead-antimony alloy, which can be cheaply converted into a punch by casting in the zinc-alloy die, is satisfactory for working temperatures up to 400 F. As in deep drawing, both drop hammer and die should be heated. A ring burner may be used in the die.

STRETCH FORMING. The possession of a very high elongation at elevated temperatures makes magnesium ideally suited to stretch forming. Punches for hot-stretch forming are conveniently made of zinc alloy if temperatures do not go too far above 400 F. The punch can be heated by means of gas burners, and the sheet can be preheated in an oven and kept hot during forming by means of contact with the punch.

BENDING. Magnesium sheet and extrusions can be bent with the same type of tools customarily used for other metals. Bending rolls are used on sheet for such operations as the production of cylindrical tanks. Pipe-bending machines of standard design are suitable for bending magnesium tubing. Press brakes and folding-leaf-type brakes are being used for magnesium sheet. Other extrusions such as bars, rods, and shapes are bent by the same methods as those used for aluminum and other metals. When heating of the stock is necessary for making bends, the heat can be applied in any convenient manner. On small production runs simply passing a torch over the work may be adequate. On long runs, and where the equipment permits, electric strip heaters can be attached to bending brakes. The desirable working temperature for annealed magnesium sheet and extrusions is 500 to 650 F. Sheet in the hard-rolled condition should not be heated over 400 F lest annealing result. A contact pyrometer should be used to check the temperature of the material. In case such an instrument is not available, the crude but effective temperature indicators known to many metal workers can be substituted. Typical of them are: A smear of laundry soap on the metal turns dark brown at about 400 F; a mark made with blue carpenter's chalk will lose its color at approximately 600 F.

SPINNING. When the quantity of shaped magnesium parts does not justify the cost of die equipment for deep and shallow drawing, spinning can sometimes be substituted.

When heating seems desirable to improve the workability of the metal, an ordinary welding torch may be used.

17. SURFACE FINISHING

The finishing of magnesium is of two types—protective and decorative. Protective finishing includes a chemical treatment which passivates the surface, followed by the application of paints. Decorative finishing makes use of the many attractive paint finishes used for the purpose or it might be simply a chemical treatment followed by a clear lacquer to provide durability.

CLEANING. Proper surface cleaning is a very important consideration prior to either protective or decorative finishing. For this purpose solvent-type cleaners, such as vapor degreasers, or alkaline cleaners applied by soaking in hot solutions, can be used. The magnesium also may be simply dipped in solvents. The hot alkaline cleaners have the advantage that they also remove any previously applied chemical finish or old paint coatings. Solvent and alkaline cleaners function to remove oil and grease. The cleaning of the surface to remove any oxide coatings, surface contamination, and previously applied chemical finishes can be accomplished by acid pickling or mechanically by wire brushing, sanding, sand blasting, and the like.

PROTECTIVE CHEMICAL TREATMENTS. Two protective chemical treatments are most commonly used for magnesium. One is the chrome-pickle treatment which is applicable to practically all forms of magnesium in order to provide protection during shipment and storage. It also makes a satisfactory base for a subsequently applied paint coating. The treatment consists of about a one-minute dip in a solution containing 1 $^1/_2$ lb of sodium dichromate and 1 $^1/_2$ pints of concentrated nitric acid and water to make 1 gal of solution. The protective value of the finish produced in this solution can be improved by boiling parts after treatment in a water solution containing 1 $^1/_2$ lb of sodium dichromate and $^3/_4$ oz of magnesium fluoride per gallon of solution. After treatment, parts should be rinsed in cold running water and then dipped in hot water to facilitate drying.

The other chemical treatment is known as the dichromate treatment. It is used also as a base for paint coatings. The treatment does not remove metal, as does the chrome pickle, and, therefore, can be used on parts which have been machined to close dimensions. The dichromate consists of two steps. Parts are placed for 5 min in a solution prepared by diluting one volume of 48 to 52% hydrofluoric acid with two volumes of water in a lead-lined tank. Hydrofluoric acid must be handled with care to avoid contact of the acid with the skin and to avoid inhalation of the fumes. The bath should be maintained at a temperature between 70 and 90 F during use. Upon removal from the hydrofluoric acid bath, parts should be thoroughly rinsed in cold running water and then boiled for 45 min in a dichromate bath, which is easily prepared by dissolving a pound of sodium dichromate in a gallon of water. After this, parts are thoroughly rinsed in cold running water, dipped in hot water, and allowed to dry. They are then ready for painting.

PAINTING. After the application of one of the two protective chemical treatments just described, magnesium parts are ready for painting after thorough rinsing and drying. The method of applying paints is not different from that used on other metals; in fact, the same materials can be used for most purposes. Coastal exposure or indoor locations subject to corrosive conditions require the use of inhibitive-type primer and additional top coats. Zinc yellow is the most effective pigment for use with magnesium.

The refinishing of magnesium does not require special consideration, unless the old paint has been removed by sand blasting or other methods which expose portions of the metal. Such areas of exposed metal should be chemically treated before painting is attempted. Small parts present no problem because they can be stripped of their paint and chemically treated by dipping. Objects too large to be dipped, however, require that a freshly prepared chrome-pickle solution be brushed onto areas from which the loose paint has been removed and underneath which the metal has been sanded until bright.

Assembly protection is an important consideration too, since contact between magnesium and dissimilar metals should be avoided. Such dissimilar metal contact can result in what is known as galvanic corrosion. Two or three coats of paint or plastic sealing and caulking compounds are recommended at the point of contact between magnesium and other metals.

DECORATIVE FINISHING. Decorative finishes for magnesium, as their name implies, are used to provide ornamental effects. When paints are used, and they should always be applied over the chrome-pickle or dichromate treatment, decorative finishes can provide protection as well as enhanced sales appeal. At other times, however, they may provide little or no protection and should be used only for mild service.

Mechanical Finishes. Scratch brushing, buffing, sanding, and similar mechanical methods impart a luster to magnesium surfaces prior to subsequent chemical finishing. The use of a clear lacquer directly over mechanically cleaned surfaces is not recommended for long service.

Chemical Finishes. A bright metallic luster which, when protected by clear lacquer, provides an attractive effect is produced by a chemical treatment known as bright pickle. It is applied by immersing the part in the following solution for 2 to 5 min at 70 to 80 F. It is necessary that the magnesium part be given a thorough alkaline cleaning before treatment.

Chromic acid	1 $1/2$ lb
Sodium nitrate	4 oz
Magnesium fluoride	$1/3$ oz
Water	to make one gallon

Upon removal from this solution, parts should be neutralized by being dipped momentarily into a water solution containing 6 oz per gal of sodium carbonate, after which they should be thoroughly rinsed in cold running water, dipped in hot water, and then allowed to dry. Clear lacquer should be applied immediately. Electrochemical methods produce the best decorative coating. One method is an anodic treatment which provides a coating that can be colored with organic dyes. Methods of electroplating have also been worked out, and electrodeposited coatings of nickel, chromium, and other metals can be applied to magnesium.

NICKEL AND ITS ALLOYS

By R. D. Faber

Nickel is distributed widely in the earth's crust, but in only a few places are there economically workable ore bodies. Its major uses are as an alloying element in hardenable steels, stainless steels, corrosion-resistant and high-temperature alloys, cast-iron, and other alloys such as copper-nickel, "nickel silvers," and aluminum-nickel. The metal and many of its alloys are silvery-white, corrosion-resistant, malleable, ductile, and can be processed into forgings, rods, bars, tubes, plates, sheet, strip, and wire. To its more than 3000 alloys, nickel imparts strength, toughness, ductility, increased resistance to oxidation and to corrosion, and in a few cases special magnetic, magnetostrictive, and thermal-expansive characteristics.

CLASSIFICATION. Nickel and its alloys may be classified into the following groups on the basis of chemical composition (Ref. 1).

Nickel. (1) Pure nickel, electrolytic (99.95% Ni); (2) commercially pure wrought nickel (99.4% Ni); (3) nickel shot and ingot (99.6% Ni); (4) anodes (99% Ni); (5) coinage (99.4% Ni).

Nickel and Copper. (1) Low-nickel alloys (2 to 13% Ni); (2) cupro nickels (10 to 30% Ni); (3) coinage alloy (25% Ni); (4) electrical resistance alloy (45% Ni); (5) nonmagnetic alloys (up to 60% Ni); (6) high-nickel alloys, Monel * (over 60% Ni).

Nickel and Iron. (1) Wrought alloy steels ($1/2$ to 9% Ni); (2) cast alloy steels ($1/2$ to 9% Ni); (3) alloy cast irons (1 to 6 and 14 to 36% Ni); (4) magnetic alloys (20 to 90% Ni): (*a*) temperature-compensating alloys (29.5 to 32.5% Ni) and (*b*) high-permeability alloys (49 to 80% Ni); (5) nonmagnetic alloys (10 to 20% Ni); (6) clad steels (5 to 40% Ni); (7) thermal expansion alloys: (*a*) low expansion (36 to 50% Ni) and (*b*) selected expansion (22 to 50% Ni).

Nickel and Chromium. (1) Electrical resistance alloys (80% Ni); (2) electromotive alloy (90% Cr).

Nickel and Aluminum. (1) Cylinder head and piston alloys (2% Ni); (2) low expansion alloys (1 to 2.5% Ni); (3) bearing alloy (1% Ni).

Nickel, Chromium, and Iron. (1) Stainless steels (2 to 25% Ni); (2) heat-resisting alloys (12 to 85% Ni); (3) electrical resistance alloys (35 to 60% Ni).

Nickel, Copper, and Zinc. (1) "Nickel silvers" (5 to 30% Ni).

Nickel, Copper, and Tin. (1) Nickel brasses, and bronzes (1 to 15% Ni).

Other Alloys. (1) Age-hardenable alloys (0.5 to 98% Ni); (2) nickel-manganese alloys (94 to 98% Ni); (3) nickel-molybdenum alloys (55 to 80% Ni); (4) nickel-silicon alloys (95 to 98% Ni).

The following summary is concerned with commercially pure nickel, nonferrous alloys containing more than 50% nickel, and a few alloys containing less than 50% nickel, such as "nickel silvers" and cupro nickels.

---

* Includes a small amount of cobalt.

18. NICKEL

Nickel is used in cast as well as wrought forms. Mechanical properties of nickel in various forms are listed in Table 5. Commercial, wrought nickel has a nominal nickel content of 99.4%, this includes a small amount of cobalt, less than 1%, which is counted as nickel because its effect upon the significant properties of nickel is slight and not detrimental (Ref. 2). The mechanical properties (Table 5), resistance to corrosion, and thermal and electrical conductivities of nickel are good. Its modulus of elasticity and thermal expansion are comparable to those of steel.

Table 2. Mechanical Properties of Nickel Alloys

Nickel has many uses in the chemical, soap, caustic, and allied industries for the construction of evaporators, tanks, jacketed kettles, heating coils, tubular condensers, and various other processing equipment. Nickel is noteworthy for its resistance to hot concentrated caustic soda, chlorine, and fluorine gases at temperatures up to 1000 F. It is useful for magnetostriction devices and has various applications in the incandescent lamp and radio industries. Nickel is also available in cast form and in the form of clad steel.

"L"* Nickel is wrought "carbon-free" nickel. It is softer than regular nickel, does not work-harden as rapidly, and finds special applications as base metal for high-quality rolled gold plate in the jewelry and optical industry, as containers for fused oxidizing salts, difficult deep-drawing and spinning applications, and crucibles and combustion boats for analytical laboratory use.

Duranickel * is a wrought, age-hardenable nickel alloy possessing high strength and hardness in addition to the resistance to corrosion characteristic of nickel. It is used for springs, diaphragms, radio antennae, extrusion dies in the plastic and textile fields, pump parts, and many other special applications requiring corrosion resistance together with high mechanical properties.

"E" * Nickel and "D" * Nickel contain 2.0 and 4.5% manganese, respectively; the manganese increases resistance to oxidation in sulfidizing atmospheres. "D" Nickel is used for ignition tubes, carbon arc electrode holders, and radio tube grids. "E" Nickel is used for furnace lead-in wires and support wires in incandescent lamps.

ELECTROPLATING. Approximately 10% of the total annual production of nickel is consumed by electroplating processes. Nickel can be electrodeposited to develop mechanical properties of the same order as wrought nickel; however, special plating baths are available which will yield nickel deposits possessing a hardness as high as 450 Vickers (425 BHN). Other types of plating baths in commercial use will yield bright, rather hard deposits which may require no further buffing. Adherent bonds, approaching the strength of the metal, can be developed between the nickel plate and ordinary steel, and very strong bonds may be secured to copper, brass, aluminum, zinc, and numerous other metals and alloys, including the stainless steels and Inconel. Nickel electroplate may be used to facilitate or enhance the silver brazing of various chromium-content alloys.

Very heavy nickel electrodeposits are employed for building up worn or overmachined parts. These parts can then be finished with a chromium plate or special hard nickel plate where high surface hardness is required. Special nickel shapes, difficult or virtually impossible to produce otherwise, are electroformed by depositing a heavy layer of nickel upon a suitable conducting matrix, which is subsequently removed. Electroformed nickel

dies for pressing in the sound tracks on phonograph records illustrate the fine detail which can be reproduced by the nickel electroforming process.

The most extensive use of nickel plate is for corrosion protection of iron and steel parts and zinc-base die castings used in the automotive field. For these applications, a layer of nickel, 0.0015 to 0.003 in. thick is used. This nickel plate is then finished or covered with a chromium plate consisting in thickness of about 1% of the underlying nickel plate thickness in order to maintain a brilliant, tarnish-free, hard exterior surface.

19. ALLOYS OF NICKEL

NICKEL-COPPER ALLOYS. Monel * is the most important nickel-copper alloy. It contains about two-thirds nickel and one-third copper and has high strength, excellent ductility, and good corrosion resistance to flowing salt water, dilute mineral acids, hydrofluoric, hydrochloric, sulfuric, phosphoric, and most organic acids and also strong caustic soda. Cold-worked, welded, and cast forms behave substantially the same in the above-

* Sheet and strip products are available on the basis of hardness for the various tempers shown.

mentioned corrosive media. The alloy is not resistant to corrosion by strongly oxidizing solutions such as nitric acid and ferric chloride. Monel is available in all wrought and cast forms and is used widely in the chemical and marine industries. It is also available in the form of Monel-clad steel plates. Mechanical properties of Monel in various forms are listed in Table 6.

"R" * Monel contains approximately 0.035% of sulfur, which is added to secure improved machinability, particularly in automatic screw-machine operations. It is produced only in wrought forms.

---

* Registered U. S. Patent Office.

"K" * Monel is an age-hardenable wrought alloy which has mechanical properties comparable to those of heat-treated alloy steel of the same order of hardness, and resistance to corrosion similar to that of Monel. It is nonmagnetic down to −150 F and is used for aircraft parts, turbo-pump shafts, marine-equipment parts, steam and hydraulic valve disks and seats, sleeve bearings, diaphragms, and spring parts.

"KR" * Monel is a wrought alloy which contains a higher carbon content than "K" Monel. The higher carbon results in improved machinability.

"H" * Monel and **"S" * Monel** are two cast age-hardenable alloys containing 3 and 4% silicon, respectively. They possess the general corrosion resistance of this copper-nickel group of alloys together with improved resistance to galling and erosion for applications which must withstand severe abrasion as well as corrosion. Such applications are valve seats and plugs, bushings, pump liners, and sleeve bearings, and other sliding or moving elements.

Constantan and the cupro nickels and their modifications, marketed under various trade names (e.g., Advance, Copel, Cupron, Excelsior, Jelliff Alloy 45, Chase Cupro-nickel 70-30, Cupro-nickel Alloy No. 510, Super Nickel-701), are best known for their electrical-resistance and corrosion resisting characteristics. The 70-30 cupro-nickel alloy, and to a lesser extent the 80-20 alloy, resists impingement corrosion in sea-water condensers. Their applications include marine-turbine condensers and power-plant condensers, feed-water heaters, salt-water lines, and salt evaporators in the chemical industry. The 75-25 cupro nickel is extensively used as a coinage alloy. Constantan, containing 55% copper, possesses a coefficient of electrical resistivity which is near zero and has a high thermoelectric potential against copper, iron, and nickel-chromium alloys. It is used principally for electrical resistors, thermocouples, and thermocouple lead-in wires.

"NICKEL-SILVER" ALLOYS, formerly called German silvers, are ternary copper-nickel-zinc alloys which contain no silver. More than 200 compositions are known by a wide variety of trade names (e.g. Adnic, Ambrac 850). They contain copper 52 to 80%, nickel 5 to 30%, and zinc 5 to 35%. Nickel imparts a silver-white color to these copper-base alloys and improves their strength and resistance to corrosion. The whiter alloys of this group contain about 18% or more of nickel; other alloys contain approximately 12% of nickel.

The nickel silvers are used largely for silver-plated tableware, jewelry, springs, key stock, optical frames, watch parts, marine fixtures, plumbing fixtures, and architectural trim. In some cases they are employed as electrical resistors.

NICKEL-SILICON ALLOYS. The best-known commercial alloy in this group is Hastelloy D.* It contains approximately 10% silicon and is available only in the cast condition. This alloy is strong, tough, and extremely hard; it is not recommended for any machining operations and must be finished by grinding. Its outstanding characteristic is excellent corrosion resistance to hot and cold sulfuric acid of all concentrations; it also possesses good corrosion resistance to other acids such as acetic, formic, and phosphoric.

NICKEL-CHROMIUM ALLOYS. The principal material in this group is an 80-20 nickel-chromium alloy, known by various trade names (e.g., Alray A, Chromel A, Nichrome V, Tophet A, Evanohm), which was developed to give maximum life as an electrical heating element at temperatures up to 2100 F and for electrical resistors at moderate temperatures. The 10% chromium alloy, Chromel P,* is widely used as one component of the Chromel-alumel thermocouple.

NICKEL-IRON ALLOYS. Nickel and iron are completely soluble in the liquid or solid states. Alloys of these elements are ferritic or austenitic, depending principally upon their nickel content, and are known and used chiefly for their magnetic, thermal-expansion, and thermoelastic characteristics.

The alloys containing 70 to 80% nickel (e.g., 4-79 Moly Permalloy, Hy Mu 80, Mumetal) possess extremely high initial permeability (about 20,000), high maximum permeability, and low hysteresis loss when annealed in exceptionally pure dry hydrogen at about 2060 F, followed by slow cooling. Saturation magnetization for this alloy is about 8500 gauss. They are used for cores in loading coils, filters, magnetic shields, pulse and high-frequency transformers where high initial permeability is required. The 50-50 nickel-iron alloys (e.g., 45 Permalloy, 52 Alloy, 4750 Metal, High Permeability 49, Hipernik, Nicaloi) have quite high permeability and can be used at higher flux densities than the 70 to 80% nickel-iron alloys. Because their saturation value is about 15,500 gauss they are employed usually as cores in audio and current transformers, and magnetic amplifiers.

The alloys with 36 to 50% nickel (e.g., Bethlehem No. 6, Gamma Nickel Steel, Invar 36, Nilvar) comprise those special-purpose alloys with low or controlled thermal expansion and thermoelastic characteristics. In this group are the Invars (36% Ni) and the alloys containing 42% Ni (e.g., Allegheny 42, Bethlehem No. 7, Low Expansion 42). Modifica-

* Sheet and strip products are available on the basis of hardness for the various tempers shown.

tions of the latter, containing about 5% chromium, are used to seal to soft glass. In hard glass, Kovar * (about 29% Ni, 17 Co, remainder Fe) is used (e.g., 14 Alloy, 426 Alloy, Alloy No. 4, HC4 Alloy, Kovar, Fernico). Two of the alloys in this group are age hardenable, and their thermoelastic characteristics can be controlled closely by thermal treatment; Ni Span C,* which has a constant modulus of elasticity over a moderate range of temperature (0 to 200 F) is used for hair springs in chronometers and watches.

The magnetic temperature-compensating alloys (e.g., Carpenter Temperature Compensator 30, Super Nilvar) contain 29 to 33% nickel and are used as magnetic shunts in automotive voltage regulators, aircraft tachometers, and watthour meters.

All the nickel-iron alloys may contain one or more additional elements, such as chromium, copper, molybdenum, and cobalt in order to enhance or modify the aforementioned characteristics.

---

* Registered U. S. Patent Office.

NICKEL-CHROMIUM-IRON ALLOYS. The many alloys in this group contain 78.5 to 60.0% nickel, 13.0 to 18.0% chromium, and the remainder principally iron.

Inconel * contains 77% nickel and 15% chromium, has high mechanical properties, excellent resistance to many corrosive media and to oxidation at temperatures up to 2200 F, and is used extensively both in oxidizing and carburizing atmospheres at elevated temperatures. Mechanical properties are listed in Table 7. An age-hardenable modification, Inconel "X",* is suitable for gas-turbine, supercharger, jet-propulsion, and other applications in the temperature range of 1200 to 1500 F. This precipitation-hardening alloy will maintain most of its room temperature strength properties up to 1000 F.

Alloys containing essentially 60 to 65% nickel and 15 to 20% chromium are available under a variety of trade names such as Nichrome,* Chromel C,* Tophet C,* and others; † they are used chiefly for heat-resisting purposes.

NICKEL-MOLYBDENUM-IRON ALLOYS. Hastelloy A * and Hastelloy B,* available in both wrought and cast forms, possess high mechanical properties and resistance to corrosion. Hastelloy A,* and others ‡ containing approximately 20% molybdenum, resists hydrochloric acid at moderate temperatures, and dilute sulfuric acid. Hastelloy B,* and others § containing about 30% molybdenum, has excellent resistance to boiling hydrochloric acid and wet hydrogen chloride gas, and resists boiling concentrated phosphoric acid. Optimum corrosion resistance is developed by a high-temperature solution anneal (2125 F), followed by quenching. The alloys are used in chemical and allied industries for equipment to handle, transport, and store acids and other corrosive materials.

NICKEL-CHROMIUM-MOLYBDENUM-IRON ALLOYS have outstanding resistance to strong oxidizing acids and salts. Hastelloy C is used to resist corrosion by dilute nitric acid up to 150 F and by cold solutions of nitric acid containing various amounts of ferric and cupric salts, hydrochloric, and/or sulfuric acids. Illium R and Illium G resist both sulfuric and nitric acids over a wide range of concentration and temperature conditions.

20. FABRICATION OF NICKEL ALLOYS

The working methods for the nickel alloys are determined by the chemical composition, mechanical properties, and physical constants of the materials, particularly strength, hardness, toughness, and thermal conductivity.

The high-nickel materials are stronger, harder, tougher, and work-harden more rapidly than low-carbon steel, copper, brass, aluminum, and aluminum-base alloys. In general, fabrication methods are more similar to those used for steel than for the softer nonferrous materials. Heavier equipment is required for forging, deep-drawing, and spinning, and the materials must be annealed more frequently during cold-working operations.

In hot-working operations, the high melting points of the nickel materials require temperatures that are practically identical with those used for steel; in addition, heating atmospheres which are sulfur-free are required because of the embrittling effect of this element upon nickel. Annealing temperatures for all the high-nickel materials except pure nickel are considerably higher than those required for the common steels. Bright annealing of the chromium-free alloys is easier than with steel.

The procedure for age-hardening is essentially the opposite of that for steel; the four nickel age-hardenable alloys are soft when quenched from high temperatures and are hard when held at and cooled from intermediate temperatures. The other commercial high-nickel alloys have the same hardness whether quenched or slowly cooled.

The different physical and mechanical characteristics of the nickel alloys require slight modifications for welding procedures from those employed for steel. In general, the welding of the nickel alloys is characterized, in contrast to the welding of steel, by less penetration and the need for attention to cleanliness and more skill in manipulation. Resistance welding requires less current because of the high electrical resistivity which is characteristic of most high-nickel alloys, particularly those containing chromium, molybdenum, aluminum, and titanium.

The high-nickel materials are not difficult to machine, although the combinations of toolings, speeds, feeds, and cutting compounds required are different from those used with steel or brass. The methods for deep-drawing, spinning, shearing, perforating, and tube and pipe fabrication require little modification of the standard technique for steel. Pickling is quite different because the high-nickel materials are strongly resistant to many acids, particularly those used for steel and the high-copper alloys. Further fabrication details will be found in Refs. 3, 4, and 5.

21. LOW- AND HIGH-TEMPERATURE PROPERTIES OF NICKEL ALLOYS

At subzero temperatures, the nickel alloys have strength and hardness without sacrifice of ductility and toughness. Current research in the field has developed the low-temperature mechanical values for the high-nickel alloys shown in Table 8.

Table 8. Mechanical Properties at Low Temperatures

* Values in this table are not to be considered ultimate design values. These data may be considered a basis for good design practice where the safety factors accepted today are applied.

High-temperature properties of materials have become of extreme importance during the recent years of inventive development and design. Table 9 gives the short-time tensile as well as creep data for the nickel alloys shown. Although some engineers still use short-time tensile data, such data are now considered unreliable design criteria for applications at elevated temperature; design values based on long-time creep tests are to be preferred.

ZINC AND ITS ALLOYS

By E. A. Anderson

Zinc is produced commercially as slabs, anodes, strip, sheet, wire, powder, and rod. It is consumed in the form of stampings, die castings, and other fabricated shapes. It is also used in the form of anodes for electrogalvanizing and as coatings on steel.

22. SLAB ZINC AND ITS USES

ASTM Standard Specification B6-46 for slab zinc (Spelter) gives the values of Table 1 for the various grades of slab zinc.

Table 1. Standard Specification of Slab Zinc

Grade		Maximum Allowable Percentages of Lead	Cadmium	Iron	Aluminum	Lead + Cadmium + Iron Not to Exceed
1a	Special High Grade	0.006	0.004	0.005	None	0.010
1	High Grade	0.07	0.07	0.02	None	0.10
2	Intermediate	0.20	0.50	0.03	None	0.50
3	Brass Special	0.60	0.50	0.03	None	1.0
4	Selected	0.80	0.75	0.04	None	1.25
5	Prime Western	1.60	.....	0.08	.....	.....

GALVANIZING is the process of coating iron and steel with zinc as a protection against corrosion. The product is known as galvanized or zinc-coated iron or steel. Zinc coatings are desirable not only because the zinc corrodes more slowly than iron but also because at cut edges or similar discontinuities in the coating the zinc, being anodic to the iron, affords galvanic protection and the iron is not corroded until the zinc has been removed completely for some distance by corrosion. The distance over which zinc will protect iron galvanically depends on the conductivity of the moisture in contact with the couple and is greatest in moisture having the highest conductivity.

The overall protection afforded by zinc depends largely on the thickness of the coating. For protection indoors, a few tenths of an ounce per square foot of surface is sufficient. For outdoor service, a coating of at least $^{3}/_{4}$ oz per sq ft of surface and preferably 1 oz or more is necessary.

The less pure grades of zinc commonly are used for galvanizing. Unless special coating procedures are used, however, the coating so produced will not withstand much deformation without cracking and flaking. High Grade and Special High Grade zinc, nearly free from cadmium, are used for galvanizing bridge wire, telegraph wire, and other products that are subject to major deformation such as twisting. Regardless of the method of application, the life of zinc coatings has been shown to be directly proportional to the thickness or weight of the coating. The proportion of zinc to zinc-iron alloys in the coatings has no demonstrable effect.

Specifications and Tests for Galvanized Coatings. The amount of zinc on galvanized articles is usually expressed in terms of ounces per square foot of surface excepting for sheet, where the figures are given as ounces per square foot of sheet, that is per 2 sq ft of surface. One ounce per square foot of surface corresponds to a thickness of 0.00174 in. For details of methods of determining the weight of coating, see Standard Methods for Determining Weights of Coating on Zinc-coated Articles, ASTM Specification A90-39.

Specifications for most commercial products covering weight of coating and bend tests, when required, are available in ferrous metals, ASTM Standards, 1946, Part 1A.

Ordinary coatings on sheets range from 0.75 to 2.75 oz per sq ft of sheet. The weight of zinc per single covered surface, as for wire, for example, would be one-half this amount. Zinc coatings on pipe, structural shapes, hardware, etc., generally range between 1 and 4 oz per sq ft of covered surface. The weight of coating on wire varies with the gage of the wire and the process of covering and, except in fine sizes, will range between 0.15 and 1.25 oz per sq ft of covered surface.

METHODS OF APPLICATION. Zinc coatings are applied (1) by dipping the article in molten zinc, (2) by electrodeposition, (3) by heating in contact with zinc dust, and (4) by metal spraying.

Hot-dip Galvanizing. All adhering scale or rust is removed from the wire or steel by pickling, usually in hot sulfuric acid. A rinse and a dip in cold hydrochloric acid usually follow, but in better practice iron salts are removed from the pickled material by vigorous rinsing and scrubbing, followed, if necessary, by dipping in slightly acidulated 25% zinc chloride. After partial drying, the material enters the bath of molten zinc sometimes through a flux of zinc ammonium chloride. Interaction with the molten zinc causes the rapid formation of an adherent layer of iron-zinc alloys on the iron surface. The longer the immersion, the thicker is the alloy layer. The material is withdrawn from the zinc bath through rolls kept clean by zinc ammonium chloride flux for sheet or through charcoal, sand, or asbestos wipes for wire. A normal coating will consist of an inner layer of iron-zinc alloy reaction products and an outer layer of zinc from the galvanizing bath which has adhered to the alloy layer. Speed of withdrawal and nature of wipe influence the thickness of the layer of molten zinc adhering to the work. Tin may be added to the zinc bath to produce coatings with bright spangles. Aluminum may be added in the hand-dip galvanizing of pipes, shapes, and hardware to produce a smooth coating. The vapor of burning sulfur or ammonium chloride dust sometimes is blown over the surface of the sheets to improve coating brightness. There are a number of patented hot-dip galvanizing processes which depart in one or more ways from the above, usually in the preparation of the steel for dipping. One such process also provides for the addition of aluminum to the zinc.

Electrogalvanizing. Zinc coatings may be applied to wire, strip, conduit, hardware, and fabricated shapes by electroplating. Small articles intended for indoor use usually are plated in proprietary cyanide-type solutions capable of producing bright deposits. Sulfate and chloride baths are used in the continuous production of electrogalvanized strip, wire, etc. Special High Grade zinc anodes are required except in the patented Tainton process, which uses insoluble anodes. Electrogalvanizing avoids changes in dimensions and properties due to heat and does not produce excessive deposits in recesses, such as the base of threads, which would affect dimensional tolerances. The thicknesses of coating required for different types of service are the same as those needed in hot-dip galvanized coatings and are expressed as thickness in thousandths of an inch. ASTM Specification A164-40T covers three classes of electrodeposited zinc coating having minimum thicknesses of 0.00015, 0.0005, and 0.001 in. ASTM Specification A219-45T defines methods for measuring the thickness of electrogalvanized coatings.

Sherardizing. Zinc-rich coatings are produced on iron and steel by heating the material for several hours at 600 to 700 F in contact with zinc dust in a closed, usually rotated, vessel. The resulting coating, which is quite uniform, consists almost entirely of iron-zinc alloys, richer in iron near the base and containing some entrained zinc dust at the surface. (See also p. 3-11.)

Sherardizing may result in some heat treatment of the steel. The coatings tend to dust rather than flake when bent. Paint films adhere well. Sherardized coatings will perform equally as well in corrosive service as hot-dip or electrogalvanized coatings of the same thickness.

Metal Spraying. Sprayed zinc coatings are applied by exposing the iron or steel surface to a forcible spray of zinc particles produced in a suitable gun from zinc wire or zinc powder. Grit blasting of the steel and care in the operation of the gun are essential to good coating adhesion. By going over the same area a number of times, very heavy coatings may be built up. Care must be taken, however, to avoid thin spots. Sprayed zinc coatings tend to corrode at a somewhat faster rate than other types of zinc coatings, but this is normally compensated for by the heavier coatings applied.

BRASS. The second largest use of zinc is in the manufacture of brass. Brass alloys are discussed in detail on pp. 4-24 to 4-40. Since lead is objectionable in alpha brass for hot rolling and in brass used for drawing, grades of zinc low in lead are largely used in brass manufacture.

DIE CASTING. Suitable alloys for die casting require zinc of Special High Grade purity. Comparative freedom from lead, cadmium, and tin is essential. By alloying with about 4% aluminum, a few hundredths of 1% magnesium, and 0 to 3% copper, alloys amenable to die casting and having excellent mechanical properties in the die-cast state are obtained. (See also p. 4-79.) Alloys of this sort have also been used in the sand-cast condition as dies of large size for the fabrication of thin sheet metal, such as aluminum airplane parts.

SLUSH CASTING. Alloyed Special High Grade zinc containing 4 to 5.5% of aluminum and sometimes small additions of copper is used in the production of slush castings largely for use in lighting fixtures and other ornamental parts. Alloys of this sort are less stable than the die-casting alloys which, in turn, cannot be used satisfactorily in the slush-casting process. (See also Section 19, Article 21.)

23. ROLLED ZINC

COMPOSITIONS. ASTM Specification B69-39 lists the rolled zinc compositions in Table 2 as typical.

Table 2. Typical Rolled Zinc Compositions

Lead, %	Iron Maximum, %	Cadmium, %	Copper, %	Magnesium, %	Zinc, %
0.05 max	0.010	0.005 max	0.001 max	....	Remainder
0.05 to 0.12	0.012	0.005 max	0.001 max	....	Remainder
0.30 to 0.65	0.020	0.20 to 0.35	0.005 max	....	Remainder
0.05 to 0.12	0.012	0.005 max	0.65 to 1.25	....	Remainder
0.05 to 0.12	0.015	0.005 max	0.75 to 1.25	0.007 to 0.02	Remainder

Other compositions of a generally similar type also are available and, where consumption is large, special compositions usually can be arranged for.

CLASSIFICATION OF ROLLED ZINC. Rolled zinc is classified as follows (see ASTM Specifications B-69-39, for rolled zinc):

Type I. Coils or sheets cut from strip (ribbon) rolled zinc.
Type II. Pack rolled zinc.
Type III. Zinc plates such as boiler and hull plates produced by any rolling method.

Strip zinc may be obtained in coils or flat lengths in thicknesses of 0.004 to 0.125 in. Depending on the gage, maximum width varies from 12 to 20 in., but widths less than 12 in. are obtainable in any gage. Lengths of coil may vary from 100 to 250 ft in heavy and medium gages and up to 2000 ft and over in the lightest gage. Thicknesses below 0.004 in. are obtainable as foil. Dimensions of sheets range as follows: thickness, 0.006 to 0.10 in.; width, 18 to 60 in.; length, 72 to 144 in.

BOILER PLATES. Plates of rolled zinc, usually about 1/2 to 1 in. thick, termed boiler plates or hull plates, are attached to the inside of boilers or to the outside of steel hulls to give galvanic protection against corrosion. Cast- or rolled-zinc anodes, buried in the soil and connected to steel pipe lines by insulated wires, similarly protect the pipes. The process, frequently called cathodic protection, results in protection of the steel at the expense of the zinc which dissolves. Best results have been obtained with zinc of good purity.

ZINC GAGE. Table 3 lists the standard zinc gages together with the corresponding thicknesses and weights per square foot. The use of this special gage is discouraged, and to avoid error, the actual thickness, expressed in thousandths of an inch, is preferable. For comparison of the zinc gage with other standard gages, see p. 6-06.

ASTM Specifications B69-39 permit the following thickness tolerances:

	Thickness, in.	Permissible Variation in Thickness
Type I.	Up to and including 0.020	±0.001
	Over 0.020	±5%
Type II.	Up to and including 0.032	±0.002
	Over 0.032	±6%
Type III.	All thicknesses	±6%

Established limits for variations in length and width and for amount of curvature and bend will be found in the ASTM specification.

Table 3. Zinc Gage

Rolled Zinc Gage No.	Weight of 1 sq ft, lb	Thickness, in.	Rolled Zinc Gage No.	Weight of 1 sq ft, lb	Thickness, in.
3	0.22	0.006	16	1.68	0.045
4	0.30	0.008	17	1.87	0.050
5	0.37	0.010	18	2.06	0.055
6	0.45	0.012	19	2.25	0.060
7	0.52	0.014	20	2.62	0.070

11	0.90	0.024	24	4.70	0.125
12	1.05	0.028	25	9.40	0.250
13	1.20	0.032	26	14.00	0.375
14	1.35	0.036	27	18.75	0.500
15	1.50	0.040	28	37.50	1.000

MECHANICAL PROPERTIES AND TEST METHODS. Ordinary methods of mechanical testing have only limited usefulness in testing zinc. The strong dependence of properties on the rate and duration of loading renders the usual tensile property determinations of little value, since normal testing speeds are too low to reproduce the rates of deformation in fabricating operations and far too high to apply in cases of long-continued stressing in service. For this reason, no figure for the modulus of elasticity can be given for zinc. The best basis for designing zinc parts is the informed use of creep data (see *ASM Metals Handbook*, 1948 edition). Consultation with a rolled zinc producer on specific problems is recommended.

Since the best test for fabricating properties is behavior in actual fabrication, most rolled zinc is custom rolled to suit individual requirements. ASTM Specifications B69-39 give information on two tests, temper and dynamic ductility, which are commonly used as mill control tests and to a limited degree in purchase specifications.

Temper is measured by a testing machine that wraps a specimen tightly around a mandrel in which one end of the specimen is clamped. The degree to which the free end springs away from the mandrel is measured on an arbitrary scale ranging from zero, representing no spring whatever, to 100, representing material that returns to its original straight condition.

The three types of rolled zinc are classified according to temper: Type I, dead soft, soft, half hard, and hard; Type II, commercial; Type III, no classification. It should be noted that the terms soft, dead soft, etc., serve to designate certain specific ranges of properties regardless of the combination of composition and rolling treatment by which the properties are obtained. Table 4 gives the temper requirements of Type I and Type II rolled zinc.

Dynamic ductility is determined by forming a series of cups by forcing a spherical-ended plunger into a test strip, the plunger being adjustably mounted in a drawing press to permit varying the depth of the cup. The maximum depth of the cup in inches which can be formed where "necking down" is just visible is the dynamic ductility. See Table 4 for dynamic ductility characteristics of the various types of rolled zinc. Tensile strength is of secondary importance in the application of rolled zinc. Where such tests are required, the ASTM standard tensile specimen for thin sheet metal is entirely suitable. A free head speed of 0.25 in. per min should be used. Under these conditions, the tensile strength of rolled zinc in the direction of rolling will vary from about 18,000 psi for soft temper High Grade zinc to 35,000 psi for hard temper Prime Western zinc. Alloy zincs can be raised to higher strength levels.

The elongation will vary from 5% for the hardest to at least 65% for the softest metal. The tensile strength at right angles to the rolling direction will be higher and the elongation somewhat lower. Creep testing is of much greater importance than ordinary tensile testing in the evaluation of rolled zinc for specific applications. Much work along these lines has been carried out by rolled-zinc producers. The results have been correlated with actual loading tests on corrugated zinc roofing sheets.

FABRICATION. The ductility of zinc is high at and above room temperature but falls off rapidly at temperatures below 70 F. All drawing and bending operations should be performed at temperatures of 70 F or above. Frequently, an operation which is just too severe to be successful at temperatures near the lower limit may be successfully accomplished by warming the zinc and tools, for example, to 100 F. In any type of extrusion, it is necessary to use an elevated temperature in order to operate with reasonable pressures.

Table 4. Dynamic Ductility and Temper, Types I and II Rolled Zinc

American Zinc Gage No.	Thickness, in.	Type I								Type II	
		Dead Soft		Soft		Half Hard		Hard

17	.050	.355		.335		.310		.260		.260	...

For certain ornamental sheet metal work, heavy gage zinc is hand formed at temperatures as high as 480 F.

Lubrication. In all operations where a lubricant is required, excepting those involving temperatures well above 70 F, soapy water is the cheapest lubricant and is quite satisfactory. A neutral soap should be used to avoid staining. If finish is important, it may be necessary, in order to avoid spotting, to wash the work and dry it in sawdust. Loading or building up of zinc deposits on the tools sometimes occurs. This may be minimized by including a small amount of a very fine abrasive such as French chalk in the drawing lubricant.

Bending usually is performed either on an ordinary brake or in forming rolls. In a brake, the edges of the bending and clamping jaws should be rounded as much as possible, at least to the extent of removing the sharp edge. If possible, bends in rolled zinc should be at right angles to the grain or rolling direction. It then is easy to obtain proper bending properties without the sacrifice of hardness and stiffness.

Bends frequently must be made with the bend axis in the rolling direction because of width limitations in strip zinc or to take advantage of automatic machinery using coils of ribbon zinc. Zinc manufacturers should be consulted in regard to the best combination of high bending properties and high stiffness for the particular conditions involved.

Temperature is most important in bending zinc as in other forming operations. A slight warming of the metal sometimes makes possible an otherwise impossible bending operation.

Drawing. Operations in which cups are formed from flat blanks without any general reduction in gage are called *drawing*. Shop methods in drawing zinc vary considerably from one plant to another, but in general brass practice is followed with departures in detail, depending on the particular operation. It is unnecessary to anneal pure zinc between operations, and the work-hardening alloys require fewer annealings than brass. Reduction in diameter from blank to the first cup should not exceed 40% in commercial operation. A somewhat lower reduction usually is preferable. It is possible to reduce the wall thickness about 10% in redrawing operations in which the cup diameter is reduced 20% or less.

Extrusion. Zinc is successfully extruded into any of the forms commonly produced by this process. Tubing and rod have been produced, but in the United States development has been limited principally to the impact extrusion of cups, buttons, etc. Blanks for the extrusion of small articles usually are punched from rolled metal, although cast billets have been used for rods. Because of the directional properties of rolled zinc, some trouble due to nonuniform flow is encountered in some classes of work. A specially rolled zinc can be supplied to minimize this difficulty.

Welding of zinc requires some care because of the low melting point and the tenacious nature of the oxide. Zinc cannot be welded without seriously weakening areas adjacent to the weld by coarse grain growth. If strength is important, some cold-working operation to refine the grain should follow welding.

Soldering. Zinc is easily soldered. Low soldering temperature is necessary to avoid excessive grain growth in areas adjacent to the joint. This is best obtained by using a large iron hot enough to accomplish the soldering with a single pass. Half-and-half solder generally is used, although solder with a lower melting point is of advantage. A solder composed of Pb 55%, Sn 30%, and Cd 15% is suitable for zinc. It has a low melting point combined with high strength. Acidulated zinc chloride or killed hydrochloric acid makes an excellent flux, although much zinc is soldered without a flux. Soldered zinc should not be remelted because the resulting tin content causes hot shortness.

Hot Stamping. Certain complicated and deep draws such as occur in ornamental sheet metal work are made in heavy gage zinc by preheating the metal to about 480 F before stamping. This work requires knowledge of the working qualities of zinc at this temperature and should be done by skilled workmen. For some uses, as in the manufacture of organ pipe, the rolled zinc is given a thorough anneal prior to working. A 30-min anneal at 480 F, while removing much of the desirable bending and drawing qualities, will reduce the metal to the very soft, nonresonant condition required for this use.

Machining. In machining zinc, it is common practice to use tools with a greater rake than is normally used and to use soapy water as a lubricant.

24. PROPERTIES OF ZINC

PHYSICAL PROPERTIES. The more important physical constants of zinc are given in Table 5.

Table 5. Physical Constants of Pure Zinc

Atomic weight	65.38
Density (cast), 77 F	7.133 g/cm^3 0.258 lb/in.^{3}
Density (rolled), 77 F	7.142 g/cm^2
Melting point	787 F
Boiling point	1663 F
Specific heat, 68 F	0.0915
Latent heat of fusion	43.4 Btu/lb
Latent heat of vaporization	767.3 Btu/lb
Coefficient of linear expansion	
Cast	21.7×10^{-6}/°F
Rolled, with grain	17.8×10^{-6}/°F
Rolled, across grain	12.8×10^{-6}/°F
Thermal conductivity	786.5 Btu/sq ft/in./hr/°F
Electrical resistance *	2.33 microhm-in.
Temperature coefficient of electrical resistance, 32–212 F	0.00232 per °F
Electrochemical equivalent	0.3388 mg/coulomb
Electrolytic solution potential vs. hydrogen electrode	−0.762 volt
Magnetic susceptibility	-0.15×10^{-6} cgs
Velocity of sound (room temperature)	12,041 ft/sec.
Crystal structure	Hexagonal, close packed
a_0	2.6594KX
c_0	4.9370KX
c/a	1.8564

* Based on soft rolled zinc strip 99.99% pure. Resistivity of strip zinc may vary 3%, depending on rolling treatment, and in commercial grades about the amount, depending on purity.

METALLOGRAPHY. The common impurities in zinc are lead, cadmium, and iron. Their importance varies individually with the use to which the metal is put. These elements as well as copper, magnesium, and aluminum, which are the ones most commonly added in zinc alloys, are discussed below.

Lead, which enters into extremely limited solid solution, has no great effect on the mechanical properties of unalloyed zinc. In zinc-alloy die castings it has the very undesirable effect of stimulating intercrystalline corrosion.

Cadmium, in the amounts present in commercial zinc, is completely in solid solution and exerts an important hardening effect. It also raises the recrystallization temperature.

Whereas pure zinc recrystallizes at about room temperature and cannot be appreciably work hardened, zinc containing cadmium can absorb considerable amounts of work hardness during cold rolling or drawing. Cadmium, like lead, stimulates intercrystalline corrosion in zinc die-casting alloys which contain aluminum.

Iron has a limited solid solubility of the order of 0.001 to 0.003%. Attention must be given to the iron content of zinc for rolling. Some iron is desirable, but excessive amounts are harmful to properties.

Copper is the alloying element most frequently added to zinc. It enters into solid solution in zinc up to approximately 1% and with about the same effect as cadmium, except that the copper-zinc alloys are more ductile and easier to roll.

Magnesium has a solid solubility ranging from 0.002 to 0.1%, but even these amounts exert a strong influence on its creep properties. When magnesium is added in the presence of copper, a striking increase in creep resistance is observed.

Aluminum. Except in carefully controlled compositions comparable to those used in die casting, zinc alloys containing aluminum are unstable when rolled. Alloys of the die-casting type held within the required limits for composition are essentially stable in either the cast or the rolled condition.

CHEMICAL PROPERTIES. Atmospheric Corrosion. Rolled zinc corrodes smoothly and uniformly in the outdoor atmosphere. The absence of pitting permits estimation of the corrosion rate from weight change data. The data in Table 6 are typical. The corrosion rate of zinc is greatest in industrial atmospheres and least in rural and desert atmospheres. Although there is a tendency for the purest zincs to have lower corrosion rates than the impure zincs, particularly in southern exposures, it is generally true that the corrosion rate of rolled zinc is substantially independent of the composition.

Table 6. Corrosion of Rolled Zinc in Typical Outdoor Atmospheres

(Data from published reports of Committee B-3 of ASTM)

Type Zinc	Corrosion Rate

† Seacoast.
‡ Rural and desert.

Aqueous Corrosion. Zinc coatings are widely used in the handling of water supplies with generally satisfactory results. Rolled zinc and zinc die castings are less commonly used in contact with water. The rate of corrosion in water is, in general, much lower than that of iron. Temperature, *p*H, and concentration of dissolved oxygen all influence the corrosion rate. The corrosion of zinc is high in acid and strongly alkaline solutions but becomes relatively low in the *p*H range 7 to 12.5. The rate of corrosion is stimulated by temperature, the effect being small for temperatures up to about 100 F and increasing rapidly at higher temperatures. Increasing concentrations of oxygen increase the corrosion rate, but very low concentrations, such as exist in stagnant water, result in rapid pitting. Carbon dioxide increases the rate of corrosion of zinc in aerated water.

Corrosion Inhibitors. The rate of corrosion of zinc in water can be reduced substantially by small additions of sodium dichromate, borax, or sodium silicate to the water. The rapid pitting type of attack which develops in contact with stagnant water can be prevented by the application to the surface of a chromate film. Such films are produced by reaction between the surface and a solution containing chromic acid or sodium dichromate suitably activated with sulfates.

Organic Substances. Zinc is inert to such common organic substances as gasoline and kerosene in the absence of water. Soaps do not attack it, although in dilute soap solutions there is a tendency to form protective films of zinc soaps. Zinc is entirely inert toward anhydrous alcohol but is corroded by mixtures of alcohol and water.

Electrochemical Properties. Zinc is a chemically active metal. It has a high electronegative potential, which is used in dry cells and in the galvanic protection of steel. Zinc anodes are used to protect steel hulls of ships and steel pipe lines buried in the ground. In contact with acids, zinc dissolves, releasing hydrogen. It forms both basic and acid radicals and is soluble both in acids and in strong alkalies.

Toxicity. Except for the salts of strong acids, which are corrosive or zinc compounds containing poisonous elements or radicals, the compounds of zinc are not toxic. Zinc is a normal constituent of many foods, and considerable excesses of zinc taken into the body are readily eliminated without ill effects. Excess zinc content in acid foods or beverages may cause unpleasant symptoms. The amounts necessary to cause such symptoms, however, are far beyond those normally encountered. The maximum safe zinc content for drinking water has been set by the U. S. Bureau of Public Health at 15 parts per million. Larger contents may be ingested safely, but the taste is unpleasantly metallic.

Plating. Articles produced from both die-cast and wrought zinc may be plated readily with any of the common plated finishes. It is customary to apply a primary copper coating to a thickness of at least 0.0002 in. before depositing other metals. For decorative purposes in use outdoors, minimum total coating thicknesses of all coats of 0.0010 to 0.0015 in. are required. Thinner coatings are suitable for indoor use.

Painting. Organic finishes do not adhere well to untreated zinc surfaces. A phosphate pretreatment such as Bonderite insures good initial adhesion and retention of adhesion. Baking enamels to be used on zinc should require relatively low baking temperatures to avoid alteration of the properties of the zinc.

THE LESS COMMON METALS

By Bruce W. Gonser and John L. Everhart

Some of the industrial applications of the less common metallic elements are summarized briefly in the following paragraphs. For more detailed information, the publications listed at the end of this chapter (p. 4-72) may be consulted. See also Table 3, p. 1-04.

ANTIMONY. This bluish-white metal is harder than copper and so brittle that it may be pulverized readily. The metal, which is a poor conductor of heat and electricity, is used almost exclusively as an alloying addition. With tin and copper it is used in bearing metals (babbitt); with tin in Britannia metal; and has been suggested for alloying with copper and nickel as an antimony worm gear bronze.

Antimony is used extensively for hardening lead. Such lead-base alloys containing antimony are applied as bearing metals and type metals (with varying content of antimony and other metals), battery plates (4 to 12% antimony), solders (up to 3% antimony), cable sheath and lead foil (1% antimony), collapsible tubes (2 to 3% antimony), and chemical equipment (12% antimony).

ARSENIC. Metallic arsenic is a brittle gray material which sublimes at 842 F without melting. The metal is used to increase the recrystallization temperature of copper (arsenical copper), in lead shot to increase the hardness and surface tension, and in insoluble lead-antimony anodes (up to 0.8% arsenic).

BARIUM, commercially available with a purity of 99.95%, is soft and malleable with a hardness similar to sodium. Barium is used as a "getter" to remove the last traces of gas in vacuum tubes and as a lead-barium-calcium bearing metal. A high-nickel alloy containing barium finds application in automotive ignition equipment.

BERYLLIUM, with a specific gravity of 1.82, is two-thirds as heavy as aluminum and is the lightest of all metals with the exception of magnesium and the alkalies. It melts at about 2350 F. The massive metal is not attacked by air at ordinary temperatures and does not tarnish in the presence of sulfur. It has a great affinity for oxygen, however, and beryllium powder, if ignited in air, burns brilliantly.

Beryllium is used for windows in x-ray tubes, electrodes in Neon tubes, in cyclotrons, and in connection with atomic energy development. However, it is applied most widely in copper-beryllium alloys. These alloys, containing usually 2 to 2.5% beryllium, are hardenable by heat treatment. The increase in strength in the copper-beryllium alloys is not accompanied by a great loss in electrical conductivity, compared to the loss obtained with many other elements which harden copper, such as silicon or tin. Beryllium-copper is used for springs in electrical applications, for nonsparking tools, and for various wear-resisting parts. The alloys are available in the form of strip, rod, wire, forgings, and castings.

Several modified alloys are available commercially also. One which contains 2.6% cobalt and 0.5% beryllium has excellent electrical conductivity and heat resistance after heat treatment and may be used for electrical contact springs that are subject to overheating. Nickel-beryllium alloys are also heat treatable to high strengths, as are several complex iron-chromium-nickel-beryllium alloys. Beryllium oxide resists thermal shock and retains its high electrical resistance at high temperatures. With a melting point of about 4660 F, it is a useful refractory for high-temperature service.

BISMUTH. This very brittle material is white with a distinct pink tinge. It expands 3.3% during solidification. The thermal conductivity of solid bismuth, 4.85 Btu per hr per ft per F, is less than that of any other metal except tellurium and mercury.

Bismuth is used most widely in fusible alloys and low-melting-point solders. A bismuth-lead-tin-cadmium alloy is employed for tube bending. The bismuth-lead eutectic alloy, melting at 254 F, neither expands nor contracts when cast into sand molds and is used for pattern duplication and the production of master patterns in foundry operations. A nonshrinking bismuth-lead-tin-antimony alloy, known as Matrix alloy, has a pouring range of 480 to 660 F. The alloy will sustain continuous loads of 5 tons per sq in. and short period loads of 8 tons per sq in. It is used for short-run dies, forming dies for sheet metal, to mount parts of complex punches and dies, and in repairing broken dies. Other applications of the high-bismuth alloys include oiltight, airtight, and watertight seals between glass and brass or copper tubing. A bismuth-tin-lead low-melting alloy is used effectively as a die by casting to shape, dipping in liquid nitrogen, and frequently redipping to maintain the high compressive strength that it reaches at low temperatures.

BORON is a light metal (sp. gr. 2.3) that is frequently classed as a nonmetal. There are only insignificant uses for the pure metal and only a few applications of boron as an alloying constituent. Ferroboron is used to add very small amounts of boron to steel (as 0.002%) since it increases the capacity of steels to harden upon quenching.

Boron carbide and boron nitride are the hardest materials known, next to the diamond. As such, they are used where erosion is extreme, as for sandblasting nozzles. Boron is used as a constituent in some hard-facing alloys.

CADMIUM is a soft ductile metal with a bluish-white color, having a melting point of 610 F. It is used most extensively as a protective coating for steel. It is a constituent of a number of low-melting alloys employed as solders or as fusible plugs in sprinkler systems, also of a number of silver (hard) solders. Cadmium-silver and cadmium-nickel alloys have been used as bearing metals. To improve the strength and wear resistance without seriously reducing the electrical conductivity, 1% cadmium is frequently added to copper for use in trolley wires.

CALCIUM, a silvery white metal soft enough to be cut with a knife, oxidizes rather rapidly on exposure to moist air. The addition of 0.04% calcium to lead improves the strength and resistance to fatigue, and the alloy has been used as sheathing for telephone cables. Several lead-base alloys containing calcium are employed as bearing metals, particularly in Germany. Calcium together with lithium is used to deoxidize copper because the quantities that remain in the solid copper have very little effect on the electrical conductivity.

CERIUM is a steel-gray, malleable, and ductile metal. It is used as an alloying element, particularly in magnesium to enhance high-temperature properties, and (in very small percentages) in such alloys as 80 nickel-20 chromium electrical resistance elements where it is claimed to give longer life at high temperatures.

Misch metal, the most used commercial alloy (containing cerium and other rare earths with varying quantities of iron), is brittle and pyrophoric. It is used in the manufacture of lighter flints, tracer bullets, and other ignition devices, as well as an alloying addition to the light metals and as a less expensive substitute for cerium alone.

CHROMIUM is a highly lustrous white metal with a distinctly bluish tinge, having a specific gravity of 7.1 and a melting point of about 3380 F. High-purity chromium is sufficiently ductile to be drawn into wire. Because of its excellent resistance to atmospheric corrosion and tarnishing, chromium is used extensively in plating other metals for decorative purposes, particularly in the automotive industry. Being very hard and wear resistant, chromium plating is applied also to increase the life of machine and engine parts punches, dies, and gages. The resistance of chromium to corrosion makes the plate valuable in the chemical industries.

Chromium is a constituent of the most widely used stainless and heat-resisting steels and is applied broadly in the low-alloy steel field. Nickel-chromium alloys are used for electrical resistance elements. Alloys consisting primarily of cobalt, chromium, and tungsten form a class of high-speed cutting tools. Chromium (up to 1%) is added to copper to increase the strength without greatly reducing the electrical conductivity. A number of chromium-base alloys are under development for severe service at high temperature.

COBALT is a fairly hard metal resembling nickel in many of its properties. It has a specific gravity of 8.9 and a melting point of about 2695 F. Cobalt is highly magnetic, being second only to iron in this property.

Many of the alloys developed in modern times for cutting tools or for wear resistance contain cobalt. They include high-speed steels, various tool and die alloys, stellite, and the cemented carbides. Cobalt is used extensively in permanent-magnet alloys. A cobalt-chromium-aluminum alloy is one of the principal electrical-resistance materials. Potentially, the most important application of cobalt lies in cobalt-base alloys for severe service at high temperatures. These alloys, usually precision cast to shape, are characterized by their resistance to wear, heat, corrosion, and erosion. During the war, supercharger blades for operation at 1500 F were cast from an alloy containing about 60 to 65% cobalt.

COLUMBIUM. This light-gray ductile material is approximately as hard as wrought iron. It can be hardened locally or throughout by heating in nitrogen, hydrogen, carbon-bearing gases, or in air. Although resistant to most chemical reagents, it is attacked by concentrated sulfuric acid and fused alkalies. Similar to tantalum in most respects, it is only about half as heavy and is not quite so resistant to corrosion by some acids.

Columbium is used as ferrocolumbium to prevent the intergranular corrosion of stainless steels at elevated temperatures.

GALLIUM. This grayish metal, of low malleability, has a specific gravity of 5.9, a melting point of 85 F, and a boiling point of 4170 F. The wide range between melting and boiling points makes gallium useful for high-temperature quartz thermometers ranging up to 1830 F. The metal, which has the property of forming exceedingly white mirrors on glass, may find application in optical service.

GERMANIUM is one of the unusual metals which only recently has become available in commercial quantities. Like bismuth, it expands slightly on freezing, and this property persists even when alloyed with as much as 92% gold. The very high electrical resistance of germanium has suggested its application as resistors, particularly as thin films of metal deposited on glass. Although germanium melts at about 1760 F, when alloyed with 88% gold, the melting point drops to 672 F. Such low-melting gold alloys make good solders for gold, and good dental and jewelry castings. Germanium is chiefly used, however, as an electric current rectifier, as in rectification of microwaves for radar applications.

GOLD. This most ductile and malleable of all metals has a specific gravity of 19.3 and a melting point of 1945 F. It is a good conductor of heat and electricity and is highly resistant to the action of most chemicals. Coinage and jewelry applications have obscured the fact that its properties make it useful for corrosion-resistant apparatus. Considerable quantities are used for this purpose.

INDIUM. This soft and ductile white metal resembles tin in many of its properties. The metal has been electroplated on silver alloys with the aim of improving the tarnish resistance. Silver bearings are often plated with lead to avoid seizure, and indium plated over the lead to prevent corrosion of the lead by corrosive lubricating oil. The addition of 18% indium to Wood's metal reduces the melting point to 117 F and makes the alloy valuable as a very low-melting solder.

IRIDIUM is one of the hardest, most refractory, and difficult to work of the metals, although it may be forged at high temperatures. It has a specific gravity of 22.4 and melts at 4450 F. It is the most corrosion-resistant element known, being unaffected by common acids and resistant to aqua regia and fuming sulfuric acid.

It is used to harden platinum for applications in electrical contacts, for voltage regulators, high-tension magnetos, relays, etc. Iridium-platinum alloys serve as insoluble anodes in electroplating.

LITHIUM. Lightest of the metallic elements, lithium has a specific gravity of 0.53. It is a silver-white metal that in commercial purity oxidizes readily in air and reacts with water, although not so actively as other alkali metals. It is used in a number of lead-base bearing metals, particularly in Germany. Copper, deoxidized with lithium and calcium, retains a high electrical conductivity. Lithium hydride is sometimes used as a convenient source of hydrogen.

MANGANESE. Electromanganese of high purity is silver white, so hard that it is not scratched by a file, and very brittle.

In ferrous metallurgy, manganese is universally employed as a scavenger to counteract the effect of sulfur. It is applied similarly in nickel alloys. In low-alloy steels, the metal is added frequently to increase the strength. One of the earliest austenitic steels, containing 10 to 14% manganese, has very good resistance to abrasion when the pressure is high, and is applied to the manufacture of railroad frogs and crossings, rock crushers, ball-mill linings, etc.

Manganese is used to harden aluminum, primarily because it is one of the few hardening agents that do not have an adverse effect on the corrosion resistance. In copper alloys it is a constituent of the silicon bronzes and the high-strength brasses. Manganin, a copper-manganese-nickel alloy has a low temperature coefficient of electrical resistance and is used for standard resistances. In the magnesium alloys, manganese is particularly valuable for improving the resistance of the alloys to salt-water corrosion and to increase the yield strength. An alloy containing 72% manganese, 18% copper, and 10% nickel has a very high coefficient of expansion and is used as the high-expansion side in a number of bimetallic thermoregulators.

MERCURY. The only metal which is liquid at room temperature, mercury has a specific gravity of 13.5, a melting point of −38 F, and a boiling point of 675 F. It is used in mercury-arc rectifiers, mercury-vapor lamps, small dry cells (as for hearing aids), automatic control devices in industrial instruments, and scientific instruments. The mercury-vapor boiler, which operates at high efficiency, low power cost, and in small space, is an important potential application of the metal. A mercury clutch for small motors is being developed, and mercury poured into a mold and frozen is considered to have some advantages as a pattern for precision casting.

MOLYBDENUM is a ductile white metal having a specific gravity of 10.2, and a melting point of 4750 F. It can be rolled and drawn, and is available commercially in wire diameters as small as 0.002 in., and in sheets down to 0.001-in. thickness. It is used for electrical contact points, spot-welding electrodes, targets in x-ray tubes, and filament supports and grids in vacuum tubes. In an atmosphere of hydrogen, molybdenum is employed as a heating element in electrical-resistance furnaces operating up to 3600 F. Heavy molybdenum sheet is used for electrodes in glass-melting furnaces.

Molybdenum is employed widely in the low-alloy steels. It acts as a mild stabilizer of the carbides in stainless steels (18% chromium 8% nickel) and increases the strength at elevated temperatures. It also increases the resistance to corrosion by sulfuric acid and, to a lesser extent, to dilute hydrochloric acid. Molybdenum has been substituted for tungsten in high-speed steels. It is used also to improve the strength and resist the growth in cast iron at elevated temperatures. Examples of its use as a constituent in a number of nonferrous alloys are Stellite, Illium, and molybdenum-permaloy.

OSMIUM. Heaviest of the metals, osmium has a specific gravity of 22.48 and melts at about 4900 F. It is harder than glass or quartz, but is scratched by topaz. Osmium has not been worked successfully, for it is brittle even at high temperatures. However, it can be sintered at 3600 F. The principal use is in hard corrosion-resistant alloys, as for tipping pen nibs or for phonograph needles. It is applied also in special hard electrical contact materials.

PALLADIUM resembles platinum in many of its properties, but is slightly harder and stronger. It is very ductile. Like gold, it can be drastically cold worked and has been beaten into sheets $1/_{250,000}$ in. thick. The metal has excellent corrosion resistance. Palladium is used extensively for contacts in telephone relays, while base metals clad with palladium are applied in chemical equipment for the production of fine chemicals.

PLATINUM. A very ductile white metal, platinum may be worked hot or cold and has been drawn to 0.00005-in.-diameter wire. The metal has excellent corrosion resistance and retains high strength at elevated temperatures. Either massive or clad on base metals, platinum is applied in corrosion-resisting apparatus. It is resistant to the attack of molten glass and is used in furnace construction for making glass fibers. Platinum alloys are employed for resistance-furnace windings and electrical contacts.

RADIUM is a brilliantly white radioactive metal having a specific gravity of 5.0 and a melting point of about 1290 F. The metal forms a nitride on exposure to air, attacks glass and quartz, and decomposes water rapidly. It is used in therapy, as a substitute for x-rays in the examination of metals, and for making luminous dials in industrial instruments.

RHENIUM has a specific gravity of 20.5 and has the unusually high melting point of about 5730 F. Being similar to tungsten in massive form, it can be sintered at high temperatures and rolled or forged above 1470 F. It is attacked by nitric and sulfuric acids, but resists hydrochloric acid.

Electrodeposited rhenium is very hard and has been suggested for lining vessels for the transportation of hydrochloric acid. Added to platinum metals, rhenium is said to improve their ductility. It has been used in pen-point alloys.

RHODIUM. A white metal which hardly can be distinguished from silver, rhodium can be forged or swaged at room temperature and is very malleable at high temperatures. The metal is harder than silver and is resistant to oxidation and to chemical and industrial fumes.

The most important application is in plating searchlight reflectors. Plated rhodium accurately reproduces the base-metal surface; that is, a polished surface remains bright while a matte surface retains its matte finish. Rhodium alloys are used for electrical contacts, spinnerets in the rayon industry, resistance furnace windings, and high-temperature thermocouples.

RUTHENIUM, another metal of the platinum group, is hard and difficult to work, but can be forged at 2700 F. Its corrosion resistance is similar to that of iridium. It is used to harden and increase the corrosion resistance of platinum and palladium.

SELENIUM exists in four modifications; the metallic form is gray, with a specific gravity of 4.81, and a melting point of 428 F. Because of its change in electrical resistance with the intensity of light, it has been used in light-sensitive cells. Other uses are in rectifiers to convert alternating current to direct current and in free-machining copper alloys.

SILICON is the most abundant element in the earth's crust, and one which can be cheaply produced. Although possessing excellent resistance to atmospheric corrosion, even at elevated temperatures, and resistance to acids (except hydrofluoric), the use of the pure metal is negligible because of its brittleness and lack of formability. As ferrosilicon, it is a common addition to special steels, as for transformer sheet, and as a deoxidizer in ordinary steels. Silicon is also much used as an alloying constituent with copper in silicon brasses and bronzes, and with aluminum, magnesium, and their alloys.

SILVER. The whitest of all metals, silver is exceeded only by gold in malleability and ductility. In the annealed condition, silver is the best conductor of heat and electricity of the elements. It has a high resistance to attack by alkalies, organic acids, and many other elements.

The metal is used either solid or clad on base metals for corrosion-resistant equipment. Alloys are applied in electrical contacts, bearings (silver-cadmium), soft solders (silver-lead), and hard solders (silver-copper-zinc base).

SODIUM. This light, very soft metal has a specific gravity of 0.97, and a melting point of 216 F. It readily oxidizes in air and decomposes water violently. Although nearly as inexpensive as pig iron on a volume basis, there are few uses because of its great reactivity. It is used as a cooling medium in aircraft engine valves.

TANTALUM. The melting point of tantalum (about 5425 F) is higher than that of any other metal, excepting rhenium and tungsten. The metal may be worked at room temperatures, like tungsten and molybdenum, but absorbs gases readily at elevated temperatures. It can be drawn to fine wire (0.001-in. diameter) and rolled to thin sheet (0.002-in. thick). Tantalum has a chemical resistance similar to glass. It resists attack by the common acids, including hydrochloric, but is attacked by fused alkalies.

Alone or clad on base metals, tantalum is used in corrosion-resistant equipment. It is employed in the rayon industry for spinnerets and dies. Tantalum and tungsten carbides are used for tools and dies for severe service, including the swaging of molybdenum and tungsten at elevated temperatures. The solid solution of 20 atomic per cent of hafnium carbide in tantalum carbide has the highest melting point (over 7200 F) of any known material.

TELLURIUM is practically a nonconductor of electricity and, unlike selenium, shows no increase in conductivity with light intensity. Small quantities of tellurium (up to 0.1%) are added to lead to improve the strength and fatigue resistance. Even smaller additions, as 0.1 lb per ton, are remarkably effective in increasing the chill of cast iron. The metal has been used also to improve the machining properties of copper alloys and of stainless steel.

THALLIUM. A malleable metal, comparatively soft and with a low melting point (572 F), thallium resembles lead in many of its properties and is used largely in lead alloys. It tarnishes rapidly on exposure to air, yet is added to lead for better corrosion resistance. Thallium has been suggested for use in lead-base bearing metals to improve the resistance to deformation. A thallium-lead alloy is employed in electrical fuses.

THORIUM is a grayish white metal having a specific gravity of 11.5 and a melting point of 3350 F. It is readily cold worked and may be easily rolled to thin sheet. Although ductile and soft, the mechanical strength is low. When ignited, it burns brightly in air. The metal is radioactive and is subject to nuclear fission when bombarded with slow neutrons.

It is used in photoelectric cells, x-ray targets, and glow tube electrodes. Small additions of thorium to nickel-chromium resistor alloys and to platinum restrict grain growth and prolong the life at high temperature. The oxide is used to restrict grain growth in tungsten filaments. Having the highest melting point of all refractory oxides, thorium oxide is used for high-temperature furnace linings.

TITANIUM. A white metal, having a specific gravity of 4.50 and a melting point of 3275 F, pure titanium can be drastically cold rolled into strip or swaged into rod form. It can be drawn into fine wire, although its tendency to seize complicates the operation. The metal is very active and, at elevated temperatures, readily absorbs oxygen, hydrogen, nitrogen, or carbon from carbon-bearing gases. Its general resistance to corrosion is similar to that of stainless steel.

Titanium is used in stainless steels to stabilize the carbides. A nickel-cobalt-iron-titanium alloy, Konel, has high strength at elevated temperatures. The carbide, usually in combination with other carbides, is applied in cutting tools. Titanium is potentially important because of an excellent strength-weight ratio, good mechanical and corrosion-resistant properties, and abundance of ores. Many alloys, notably those with a copper base, are made precipitation-hardenable upon addition of a small percentage of titanium.

TUNGSTEN has the highest melting point (6115 F) of all the elements. It is obtained in massive form by powder metallurgical methods. After sintering, it can be hot swaged and drawn into wire. The essential practice is to work the metal from a high temperature to a low temperature to get a fibrous structure for high strength and some ductility. It is very resistant to corrosion by acids but is attacked by alkalies. The metal oxidizes rapidly at high temperatures.

Tungsten is used for electrical contacts, lamp filaments, and x-ray targets. As an alloying element, it is the principal constituent of the high-speed steels and complex nonferrous alloys for high-temperature service. Cobalt-chromium-tungsten alloys and tungsten carbide are widely used as cutting tools and dies. A sintered tungsten alloy containing copper and nickel has a specific gravity of 16.5 and is used for balancing crankshafts and for protection from x-rays. Tungsten is very resistant to attack by liquid zinc and has been used for pump parts in handling this material.

URANIUM is a silvery white metal having a specific gravity of 18.7 and melting at approximately 3075 F. The powder can be sintered and drawn into fine wire, although the fine powder is pyrophoric. It forms alloys readily with many metals and some (as 66 uranium, 34 nickel, or up to 20% uranium in copper) are resistant to corrosion, although the resistance of uranium alone to corrosion is very poor. A radioactive metal, it has been used in glow-discharge tubes and x-ray tubes, but its greatest application is in the production of atomic energy by nuclear fission.

VANADIUM. Pure vanadium is a white metal sufficiently ductile to be drawn into fine wire. Metal of this purity is not produced commercially, however, and nearly all vanadium used in metallurgy is in the form of ferrovanadium. The principal application is in steels, in which it is a carbide-forming element.

ZIRCONIUM. Zirconium is a ductile metal having a specific gravity of 6.4 and a melting point of 3370 F. It is very resistant to attack by common acids, including hydrochloric and nitric, but is attacked by hydrofluoric. Its resistance to attack by alkalies is excellent. The metal burns in air at high temperatures and, like titanium, is so reactive to all but the inert gases that it can be used effectively as a "getter" in vacuum-tube manufacture. Ductile zirconium has excellent mechanical properties, which, with its resistance to corrosion, makes it potentially a valuable material of construction.

Its uses include igniters in photoflash bulbs, primers in ammunition, electric-light filaments, filters in x-ray tubes having molybdenum targets, and in electronic applications. The excellent corrosion properties of zirconium indicate that it will be applied increasingly in corrosion-resisting equipment. It is used as ferrozirconium to a limited extent in steel metallurgy.

The oxide, zirconia, has been used as a high-temperature refractory furnace lining, as for melting chromium and platinum.

BEARING METALS

By Arthur F. Underwood

25. SELECTION OF BEARING METAL

Bearings are subjected to such varied influences that no one metal is suitable for all applications. Only by appreciating these influences and selecting an appropriate metal having the requisite characteristics can the best design be made. The individually different requirements of a bearing are (1) score resistance, (2) compressive strength, (3) deformability, including conformability and embedability, (4) fatigue strength, and (5) corrosion resistance. No order of relative importance is suggested by the listing. For one application, fatigue strength may be the predominant requirement, whereas another application can require the very best score resistance with maximum corrosion resistance. The selection of a bearing metal is usually a compromise, and the best choice is made by first recognizing what the bearing requirements are, and then selecting a commercial alloy having these qualities.

SCORE RESISTANCE. The score resistance, or anti-seizure characteristic, of metals used for bearings is often the prime requirement. Most bearings are designed to run on oil films. But metal-to-metal contact between the journal and bearing is caused by starting, stopping, deflection of the components, or heavy loads. On the other hand, many bearings operate continuously under partial or "boundary" lubrication conditions which produce rubbing contact of the surfaces. If the score resistance is not sufficiently high for the surface speed, the bearing metal will score, or ultimately seize if severe enough. At low surface speed, the heat generated at the contacts may be dissipated through the metal and heavy loads can be carried.

Experience has provided a guide to the many available metals, which is given in Table 1. Low loads are under 1000 psi, moderate loads are up to 2000 psi, and over 3000 psi is a heavily loaded bearing. Surface speeds can be considered low up to 5 to 10 ft per sec, moderate up to 15 to 20 ft per sec, and high when above 30 ft per sec. For each class a typical analysis (T) is given. It should be noted that such a general classification does not allow the inclusion of special bearing metals.

Table 1. Score Resistance and Compressive Strength of Bearing Metals

Composition, %				Order of Score Resistance	Order of Compressive Strength	Suggested Application
Cu	Zn	Sn	Pb			
85–90	(Fe: 2)	(Al: 4–10)	.....	8	1	Very poor anti-score quality. Used in minor locations.
(T) 86	(Fe: 2)	(Al: 4)				
60–90	10–40	....	0–2	7	2	Same as above. Used with hypoid gear oils.
(T) 90	9	....	1/2			
85–90	1/2–3	7–10	0–5	6	3	For heavily loaded wrist pins and similar motions where surface speed is very low.
(T) 88	2	10	.....			
80–90	0–5	3–10	5–10	5	4	Average bushing materials for low-speed, small-diameter shafts.
(T) 88	4	4	4			
(T) 80	......	10	10			
70–75	......	4–10	20–25	4	5	For moderate-speed bushings; and where lubrication is not well maintained.
(T) 72	......	4	20			
Aluminum alloys				3	6	For heavily loaded moderate-speed bearings.
Copper-leads				2	7	For heavily loaded high-speed bearings.
White metal alloys				1	8	Low to moderately loaded, low- to high-speed bearings, where dirt and deflections are present.

An increase in lead content and a decrease in zinc and tin improve the score resistance of brass and bronze. In some instances the high-score quality of white metals is utilized by plating a very thin layer of it over an intermediate coating of silver or appropriate bronze which imparts increased strength.

COMPRESSIVE STRENGTH. Especially under steady, unidirectional loads, the bearing must have sufficient compressive strength not to extrude or crack. It should be recognized, however, that fatigue strength needed by a bearing to withstand an alternating load is a separate property. In Table 1 the metals are shown in order of decreasing compressive strength. In general, decreasing strength is associated with increasing score resistance. As the inherent compressive strength becomes less, thinner layers are used to improve the effective strength. This bearing metal requirement is one which can be directly related to the physical properties found in handbooks and suppliers' catalogs. It is important to consider the effect of temperature, especially when choosing a white metal. The data for yield point and ultimate strength in Table 4 demonstrate the softening of certain commercial babbitts.

FATIGUE STRENGTH. Fatigue resistance is important for bearings subjected to alternating or rotating loads. Well-known examples are the connecting rod and main bearings of internal-combustion engines. Failure starts as small cracks at the surface of the bearing; these work down to the bonding material where they progress parallel to the backing. "Tiles" of metal are thus loosened and may be eroded away by the lubricant action. Such failures should not be confused with those resulting from poor workmanship giving bad bond, when the difficulty shows up very early and can usually be identified by no bonding material on the backing metal.

The operating conditions (especially time and temperature) and the design of the bearing housings have so much influence that it is difficult to state specific loads. In Table 2, however, a guide to the maximum load is given.

Table 2. Fatigue Strength and Deformability of Bearing Metals

	Order of Fatigue Strength	Approximate Maximum Load, psi	Order of Deformability
Bronzes	1	10,000	7
Copper-lead with tin or silver	2	3000–4000	6
Thin babbitt overlays (0.003 in. or less)	3	2000–4000	5
Aluminum alloys	4	2000–3000	4
Copper-lead	5	1500–2500	3
Cadmium alloys	6	1200–1500	2
Lead and tin base babbitts	7	800–1500	1

The method and techniques of manufacturing these metals affect their strength and fatigue life. The performance of white metals has been improved by precision manufacturing methods to obtain thin layers. Figure 1 shows the data on babbitts. The fatigue strength of aluminum alloys reaches its highest value when securely bonded to a steel back. However, long life is found with solid aluminum alloy * bearings when the shells can be made quite thick and the temperature rise in the steel housing is not sufficient to cause permanent set.

Silver is a specialized bearing material used in aircraft engines because of its high fatigue strength.

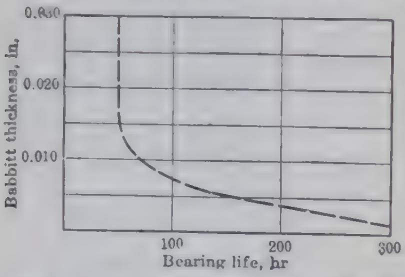

FIG. 1. Relationship between babbitt thickness and bimetal bearing life at mean unit load of 2000 psi. (Reproduced by permission from article by H. W. Luetkemeyer, *Natl. Petroleum News*, Sept. 5, 1945)

DEFORMABILITY. When loads are applied to a structure the bearings or journals deflect, often producing edge contact. If a conformable bearing metal is selected for the design, an adjustment is made without producing high temperatures that lead to a burned-out or fatigued bearing.

Second, when dirt enters the clearance space, it must embed in the bearing metal or cut a groove around the shaft and bearing. Silica (dust, core sand) or metal particles cause wear (particularly at low speed) and overheating (at high speed with hard metals). When copper-lead, bronze, or aluminum alloys are used, it is good practice to harden the journals to reduce the wear rate. White metals are preferred where dirty conditions are uncontrollable, even though such a compromise may involve a lowering of another desirable requirement.

Frequently the ability to embed when dirt is present and to conform when distortion is present are treated as separate characteristics. Because in practice a material responds about equally to each of these influences Table 2 shows this characteristic as deformability.

---

* H. Y. Hunsicker and L. W. Kempf, *SAE Quarterly Trans.*, Vol. 1, No. 1, 1947.

CORROSION RESISTANCE. Bearing metals containing unalloyed percentages of silver, copper, lead, and cadmium are subject to the corrosive attack of oils containing acids. As pointed out in Table 1, a leaded brass greatly decreases corrosion of bronze by sulfur and is to be used in designs calling for EP gear oils. Lead base alloys containing over 3% tin or suitable amounts of antimony, arsenic, or indium are protected from acidic lubricants. Cadmium bearings can be protected by small amounts of indium.

In Table 3, bearing metals are classified for their resistance to corrosion. The table should be used with discretion as the "intermediate" and "corrodible" alloys may reverse their activity in the presence of certain lubricants. By proper additives to lubricants, the possibility of bearing corrosion is greatly diminished, and the designer may specify the correct oil to be used. Lubricant specialists should be consulted.

Table 3. Corrosion Resistance of Bearing Metals

Noncorrodible	Intermediate	Corrodible
Aluminum alloys	Bronzes (high lead)	Cadmium alloys
Tin-base babbitt	Copper-lead	
Lead-base babbitt (properly alloyed)	Alkali-hardened lead	
Cadmium-indium alloys	Silver *	
Bronzes (low lead)		

* Attacked by sulfur under certain conditions.

26. COMMERCIAL BEARING METALS

BABBITT METALS. The tin-base bearing materials, often referred to as "babbitts," are among the best metal alloys as they have excellent characteristics, except the ability to carry more than low loads. Their cost is low compared to most other metals, and in relatively unimportant locations lead can be added in amounts over 18% to further reduce the expense. Specifications of ASTM grade 1 through 5 (Table 4) and SAE 10 through 12 (Table 5) cover most of the standard tin-base babbitts.

ASTM grade 1 (SAE 10) is the softest alloy and is most liable to extrusion; ASTM grade 3 is the hardest and is a good choice for high compressive loads. ASTM grade 2 (SAE 12) is recommended as a general selection, especially for designs involving fatigue loading. ASTM grades 4 and 5 contain high percentages of lead which allows a mushy eutectic to form at low temperature (370 F) and, therefore, restricts their use to very light-duty applications.

Lead-base bearings have the advantage of lowest cost but do not support as high loads as tin-base babbitt when thick linings are used. However, when the thickness is less than about 0.010 in., no appreciable difference is to be found in load-carrying ability. As with tin-base babbitts, these alloys have excellent characteristics except the loading factor. Tables 4 and 5 include the ASTM and SAE specifications. Many of these are variants of a general class. ASTM grade 7 (SAE 14) is typical of the lead-tin-antimony alloys, which are widely used for all bearing applications. ASTM grades 10, 11, and 12 are the cheapest babbitts and are serviceable for light loads. Typical of arsenical leads is ASTM grade 15 (SAE 15), which is widely used in automotive bearings where thin layers (0.002 to 0.006 in.) allow moderate fatigue loads to be carried. Alloy grade 19 is similar to the chemical composition of lining specified for car and tender journal bearings (ASTM B67).

COPPER-LEAD ALLOYS. Copper-lead bearings are backed by steel to give strength and rigidity. They are widely used where loads are higher than can be carried on babbitts. Table 6 gives the SAE specifications of standard commercial analyses. The higher lead content gives a higher score quality but at the expense of strength. Because SAE 480 has a broad lead range to cover the numerous commercial compositions the designer should specify closer tolerance for purchasing.

To obtain higher fatigue strength, tin up to 3% and silver up to 5% are added, at the sacrifice of score quality. This result can be offset by overplating a thin coating of lead alloy.

BRONZES. Bronzes are especially valuable because of their low cost and wide range of bearing characteristics as determined by the many various compositions. They are especially resistant to wear when used with hard shafts.

The number of commercial bronze alloys is very large. The SAE specifications in Table 7 can be used as a guide in conjunction with Table 1, which gives typical classifica-

* The compression test specimens were cylinders 1.5 in. in length and 0.5 in. in diameter, machined from chill castings 2 in. in length and 0.75 in. in diameter. The Brinell tests were made on the bottom face of parallel machined specimens cast in a steel mold, at room temperature, 2 in. in diameter and 0.625 in. deep.

† Alloy grade No. 9 was discontinued in 1946.

‡ The values for yield point were taken from stress-strain curves at a deformation of 0.125% reduction of gage length.

§ Johnson's apparent elastic limit is taken as the unit stress at the point where the slope of the tangent to the curve is 1 1/2 times its slope at the origin.

‖ The ultimate strength values were taken as the unit load necessary to produce a deformation of 25% of the length of the specimen.

¶ These values are the average Brinell number of three impressions on each alloy using a 10-mm ball and a 500-kg load applied for 30 sec.

** The specific gravity multiplied by 0.0361 equals the density in pounds per cubic inch.

†† Also nominal arsenic 1.0%.

tions and their use. Numerous variations of these bronzes and special-purpose bronze alloys are to be found in the ASTM Standards, Part 1-B, and the *SAE Handbook*. SAE 40, 62, 64, and 68A correspond to ASTM Designations B145-4A, B143-1A, B144-3A, and B148-9A respectively.

ALUMINUM ALLOYS. Commercially two aluminum bearing alloys are available as shown in Table 8. Bearing manufacturers should be consulted for specific information on the best applications for these alloys.

Table 8. Aluminum Bearing Alloys

	Composition, %	
	750	A-750
Aluminum	Remainder	Remainder
Tin	6.5	6.5
Nickel	1	0.5
Copper	1	1
Silicon		2.5

CADMIUM ALLOYS. These alloys are used in very special designs where their added cost is justified by the increased fatigue life. Table 9 shows the SAE specifications for the two alloys which are essentially the same in practical use. These alloys are attacked by corrosive oils unless treated with indium.

Table 9. SAE Standard Cadmium Bearing Alloys

	Composition, %	
	SAE 18	SAE 180
Cadmium, min	98.4	98.25
Nickel	1.0–1.6	0.25
Silver	0.01	0.5–1.0
Copper	0.20	0.4–0.75
Tin	0.02	0.02
Lead	0.05	0.05
Zinc	0.15	0.15
Bismuth	0.02	0.02

MISCELLANEOUS ALLOYS. Oil-less bearings are important in designs where infrequent lubrication is expected. Specially prepared bronze is treated with oil or graphite. In general, low load and low speed are required for successful design.

Certain zinc-base alloys are used where the imposed conditions are low and cheapness is desired.

DIE-CASTING ALLOYS

By J. C. Fox

The necessary requirements of a suitable die-casting alloy are: (1) Physical and mechanical properties—strength, hardness, etc. (2) Permanence of properties and dimensions in use. (3) Fluidity. (4) Strength at temperatures of solidification. (5) Solidification range. (6) Low shrinkage. (7) Machinability. (8) Polishing, plating, and finishing properties. (9) Corrosion resistance. (10) Weight and cost.

The alloys used in modern die-casting practice may be classified into six main groups: lead, tin, zinc, aluminum, magnesium, and copper base alloys. The general characteristics, properties, and applications of each of these groups of alloys are given in the following pages.

27. LEAD- AND TIN-BASE ALLOYS

Table 1 shows the chemical requirements of lead and tin-base die-casting alloys under ASTM B102-44.

Table 1. Lead- and Tin-base Die-casting Alloys

(ASTM B102-44)

Alloy No.	Tin, %			Antimony, %			Lead, %			Copper, %			Other Elements, max %

* These alloys are similar to grades 1, 5, 8, and 12, respectively, of the Tentative Specifications for White Metal Bearing Alloys (known commercially as Babbitt Metal, ASTM B23). See Article 26 in this section.

LEAD BASE alloys are usually employed where a low-cost noncorrosive metal is required and where strength, hardness, and other mechanical properties are unimportant. Parts which must withstand the action of strong mineral acids, as in fire-extinguisher parts, batteries, and other similar chemical apparatus, are produced as lead die castings. X-ray equipment employs some lead die castings because of the resistance lead shows to the passage of x-rays. The high specific gravity of lead is taken advantage of in the use of lead die castings for governor weights and similar uses.

TIN-BASE die castings have been extensively used in the past for bearings, especially for automobiles. This use, however, has greatly dwindled because of the substitution of other bearing materials. Tin-base die castings are used particularly for their corrosion resistance for such parts as soda-fountain equipment, milking machines, syrup pumps, dental appliances, and surgical instruments.

The mechanical properties of both lead- and tin-base alloys are very low, and die castings of them therefore represent only a very small percentage of the total die-casting consumption. For some specific applications, such as those given above, these are quite indispensable.

28. ZINC-BASE ALLOYS

Table 2 shows the chemical composition of the three standard zinc-base die-casting alloys, covered under ASTM Specification B86-46, and also by the SAE.

Table 2. Zinc-base Die-casting Alloys

ASTM No.	Alloy XXI	Alloy XXIII	Alloy XXV
SAE No.	921	903	925
Copper, %	2.5–3.5	0.10 max	0.75–1.25
Aluminum, %	3.5–4.5	3.5–4.3	3.5–4.3
Magnesium, %	0.02–0.10	0.03–0.08	0.03–0.08
Iron, %	0.100 max	0.100 max	0.100 max
Lead, %	0.007 max	0.007 max	0.007 max
Cadmium, %	0.005 max	0.005 max	0.005 max
Tin, %	0.005 max	0.005 max	0.005 max
Zinc, %	Remainder	Remainder	Remainder

It should be noted that these three alloys, which have been adopted by all standards groups, are based on the use of 99.99+% grade of zinc, which is mandatory. They all contain approximately 4% aluminum and vary only in the copper content. Alloy XXI, having 2.75% copper, is gradually being obsoleted in favor of the other two alloys, XXIII and XXV, because the XXI alloy shows poorer aging characteristics than the others. There is little to choose between the XXIII and XXV alloys. The XXIII alloy possesses somewhat better aging properties over a long period of time, although having initially lower tensile strength and hardness than the XXV alloy. The latter alloy possesses slightly better surface corrosion resistance when used without surface protection.

The limits of each constituent of these alloys have been carefully established after many years of experience and thorough testing. Although each constituent has a minimum and maximum content specified, there is an optimum content for each that produces the best all-round results.

Aluminum. Although the aluminum content is specified from 3.5 to 4.3, the best content is considered to be about 4.0%. Aluminum appreciably above 4.30% affects impact strength. At 5.0% the alloy is quite brittle. On the low side, aluminum below the minimum of 3.50% results in poorer castability and lower physical properties

Copper increases tensile strength, hardness and surface corrosion resistance. However, copper adversely affects the ductility, impact strength, and dimensional stability on aging.

The XXIII alloy can stand a copper content up to 0.25% without loss of properties due to aging. Higher copper contents than this quantity causes the alloy to be more susceptible to the effects of tin.

The XXV alloy is not seriously affected by copper contents outside the specification limits. Copper contents appreciably above the maximum will increase surface corrosion resistance, hardness, and strength, but will show aging effects with subsequent loss of impact strength and more dimensional growth than if the copper were held at the mean amount.

Magnesium is a necessary addition to the zinc alloys, primarily to act as an inhibitor of subsurface corrosion which may occur without it. The optimum content is 0.04%, with 0.03% as the very minimum to maintain permanence of properties and dimensions. Magnesium, above 0.05% and especially approaching the 0.08% allowed in the specifications, is conducive to "hot-shortness" in casting and to lowering the impact strength.

Lead should be kept under the 0.007% maximum specified to prevent occurrence of intercrystalline corrosion. Care should be exercised in selection and use of the quality of aluminum in alloying with the zinc. No difficulty is found in holding to this maximum lead content of die castings. The aluminum used must not contain more than 0.02% lead. Contamination of lead-containing materials, such as solder, foil, cigarette papers, lead paint, must, of course, be guarded against.

Cadmium. Unless contaminated by material containing cadmium, there is no difficulty in holding to the 0.005% maximum set forth in these specifications.

Tin, like lead, promotes subsurface corrosion and it is therefore necessary to hold to a maximum limit for this element. The results of extensive experimental work on the effect of tin, in this type of alloy, establishes the maximum safe limit of 0.005%.

Iron. About 0.02% iron is soluble in the liquid zinc alloy. Iron present above this amount is combined with aluminum, which tends to rise to the surface and is periodically removed as dross. Iron up to 0.10% maximum will have no effect on the permanence of properties and dimensions. If any of the high-iron aluminum compounds should inadvertently get into the casting, they will show up as hard spots and affect machinability. This, however, can happen only by carelessness.

Contamination. In addition to the care necessary in the selection of the proper grades of raw metal used in the preparation of the zinc die-casting alloy, extreme precaution must be exercised to insure against accidental contamination by injurious metals and alloys, such as lead, tin, cadmium, bismuth, and some others.

Zinc die casting must be segregated from the casting of other alloys, particularly the casting of tin- and lead-base alloys. The presence of lead and tin materials, such as lead hammers, counterweights, matrix metal, solder, foil, tobacco wrappings, and other like articles must be prohibited to prevent possible contamination. Likewise, cadmium materials such as plated inserts and castings must be prevented from coming into contact with the molten zinc die-casting alloy.

PHYSICAL AND MECHANICAL PROPERTIES. Table 3 shows physical and mechanical properties of the XXI, XXIII, and XXV alloys, as cast. Table 4 shows average mechanical properties of the XXIII and XXV alloys from die-cast test bars cast under the best conditions, before and after normal and accelerated aging. Table 5 shows the effect of temperature on mechanical properties.

DIE CASTING OF ZINC ALLOYS. See Section 19, Article 21.

29. ALUMINUM-BASE ALLOYS

The outstanding characteristics of aluminum die castings are: (1) Low specific gravity. (2) Corrosion resistance. (3) Retention of polished luster for long periods of time. (4) Freedom from dimensional changes. (5) Retention of properties at subnormal temperatures. (6) High thermal and electrical conductivity.

This combination of properties has resulted in the wide use that aluminum die castings have reached. The average specific gravity of aluminum die castings is 2.80, which is compared with 1.80 for magnesium alloys. For many applications, especially small parts, this weight differential between these two metals becomes negligible.

The ability of a part to take and to hold a polished luster is important, and advantage is taken of this property in the finishing of many aluminum die castings, especially household utility parts, by simply polishing the casting—resulting in a final finish highly decorative and of low cost. The binary magnesium-aluminum type alloys containing 4 to 10% magnesium are superior to other types of aluminum-base alloys in this property since they are capable of producing a whiter and highly lustrous finish.

Aluminum die castings have excellent corrosion resistance in the as cast condition. When it is necessary to increase resistance to attack by corrosion media, resort can be had to the anodic oxidation treatment, which greatly enhances corrosion resistance even in salt atmospheres. Here, again, the aluminum-magnesium excel over other alloys, particularly where decorative effects through anodizing are desired.

Aluminum die castings are remarkably stable and are not subject to changes of dimensions or properties on aging. Whenever it is required to hold to extremely close machined dimensions, however, say of the order of 0.0001 in., in some applications, it may be expedient to anneal the die castings prior to machining, to relieve any residual casting stresses set up as a result of the rapid chilling of the liquid metal. A simple anneal of about 400 F for about one hour is usually sufficient to accomplish complete stability.

Aluminum is one material capable of withstanding extreme low temperatures without affecting original ductility. For this reason aluminum has found extensive use in aircraft, refrigerators, and similar equipment where temperatures as low as −60 F may be met.

Table 6 lists the compositions of the aluminum-base die-casting alloys which have been standardized by ASTM under specification designation B85-48T, together with the equivalent SAE and Aluminum Company of America numbers.

Table 6. Aluminum-base Die-casting Alloys

APPLICATIONS. Aluminum-base alloy die castings represent about 28% of the total die-casting consumption, extending to practically all industries household utilities, such as vacuum sweepers, washing machines, ironers, food-mixing devices, slicing machines, cooking utensils, and others. The automotive industry uses aluminum die castings for transmission parts, carburetors, hydraulic brake parts, and trim. The electrical industry uses them for motor housings, instrument cases and frames, and radio equipment. The optical uses extend to cameras, projectors, binoculars, and the like. There are many other industrial uses of aluminum die castings, too numerous to list here.

30. MAGNESIUM-BASE ALLOYS

The standard magnesium-base die-casting alloys shown in Table 8 are covered by ASTM B94-47T.

Table 8. Magnesium-base Die-casting Alloys

	Alloy No. AS100	Alloy No. AZ91	Alloy No. AZ91X
Aluminum, %	9.0–11.0	8.3–9.7	8.3–9.7
Manganese, min %	0.10	0.13	0.13
Zinc, %	0.3 max	0.4–1.0	0.4–1.0
Silicon, max %	1.0	0.5	0.3
Copper, max %	0.05	0.10	0.05
Nickel, max %	0.03	0.03	0.002
Iron, max %	....	....	0.004
Magnesium, %	Remainder	Remainder	Remainder

Typical physical properties which may be expected of these alloys in the die-cast state are given by Table 9.

Table 9. Typical Mechanical Properties of Magnesium-base Die-casting Alloys

Alloy	Tensile Strength, psi	Elongation in 2 in., %	Charpy Impact, ft-lb	Remarks
AS100	29,000–34,000	1–3	0.5–2.0	Good casting and good physical properties
AZ91	29,000–34,000	2–5	1–3.0	Good casting and better physical properties
AZ91X	29,000–34,000	2–5	1–3.0	Good casting, good resistance to salt-water corrosion

APPLICATIONS. Magnesium die castings are used mostly for applications where lightness, the chief characteristic of the metal (specific gravity of the foregoing alloys is about 1.81), is the main requirement, such as portable typewriters, stenotype and other business machine cases and housings, portable tools, and other portable equipment. Magnesium die castings are also used in reciprocating and moving parts for textile, conveying, and packaging machinery.

Other outstanding properties of magnesium alloys, such as ease of machinability, rigidity, vibration, and sound damping, are taken advantage of in a variety of applications.

31. COPPER-BASE (BRASS) ALLOYS

Present ASTM B176-47T covers two brass alloys for pressure die casting. These alloys have the chemical requirements indicated in Table 10.

Table 10. Copper-base (Brass) Die-casting Alloys

	Alloy A	Alloy B
Copper, %	57.0 min	63.0–67.0
Silicon, %	0.25 max	0.75–1.25
Lead, max %	1.50	0.25
Tin, max %	1.50	0.25
Manganese, max %	0.25	0.15
Aluminum, max %	0.25	0.15
Iron, max %	0.25	0.15
Other elements,* max %	0.50	0.50
Zinc, %	30.0 min	Remainder

* Of the maximum other elements specified, the amount of arsenic, antimony, and sulfur shall not exceed 0.05% for each, and phosphorus shall not exceed 0.01%.

Alloy A represents a general-purpose low-cost brass alloy with wide limits on impurities. Alloy B is a high-purity alloy capable of excellent castability and physical properties in the die-cast state.

The *minimum* tensile properties of these alloys shown in the foregoing ASTM specifications are:

	Alloy A	Alloy B
Ultimate tensile strength, psi	45,000	58,000
Yield strength, psi	25,000	30,000
Elongation, in 2 in., %	10	15

Die-cast test bars of these alloys, however, actually show far greater properties than these minimum figures. For instance, results from three laboratories on die-cast test bars of these alloys show an average ultimate tensile strength of over 60,000 psi for alloy A and over 80,000 psi for alloy B. The average yield strength for alloy A is 37,000 psi and over 50,000 psi for alloy B.

In addition to these alloys, another alloy is being extensively used, particularly for its high strength, hardness, wear, and corrosion resistance. This alloy has the following nominal composition and mechanical properties:

Copper, %	80–81.5
Silicon, %	3.5–4.5
Zinc, %	Remainder
Ultimate tensile strength, psi	85,000–95,000
Yield strength, psi	45,000–50,000
Elongation, in 2 in., %	12–20
Brinell hardness	160–180

This alloy is finding considerable use where resistance to wear is an important requirement. For this particular use, die castings of this alloy have been found to outwear other hard materials, and in a number of applications the alloy has outworn and replaced steel.

Die castings can be produced from other copper-base alloys, but present practice dictates the use of only those alloys having melting points under 1650 F. Aluminum bronze, tin bronze, low brasses, and other high-copper alloys can be readily die-cast, but the melting points and casting temperatures are too high to be practical or economical with the die materials at present available.

APPLICATIONS. The salient properties of high strength, toughness, corrosion, and wear resistance of brass-alloy die castings make them suitable for many varied uses and open to industry a source for engineering and structural parts having the accuracy, intricacy, stability, and economy afforded by the die-casting process. Automotive lock parts, synchronizer rings, brush holders, bearing caps, hydraulic brake pistons, transmission and clutch parts, electrical switchboard parts, contactors, refrigerator parts, fittings, bearings, oil-burner parts, general engineering fittings, and household hardware are a few of the applications of brass die castings.

SOLDERS

By Bruce W. Gonser

The two types of solder most generally used are lead-and-tin solders and silver solders. The latter are used in connection with high operating temperatures and for high strength. Brazing alloys of phosphorus-copper are used at temperatures between the melting point of copper and the softening range of the comparatively low-melting silver solders.

LEAD-TIN SOLDERS. The composition and melting range of lead-tin alloys used as solders and commercially known as soft solders, are given in ASTM standard specification, Designation B32-46T. Grade A solders should be used on zinc and galvanized iron, since antimony in the solder is harmful when soldering zinc.

Table 1 shows the composition and melting range of these solders. The grade of solder metal should be selected which contains the least amount of tin required to give suitable flowing and adhesive qualities for the work on hand. The alloys are completely solid below the lower point given, designated "solidus," and completely liquid above the higher point given, designated "liquidus." Between these two points the alloys are partly solid and partly liquid. Grades 30 and 35 are particularly suitable for making wiped joints because of the large pasty range.

Table 1. Composition and Melting Range of Lead-tin Solders

Alloy Grade,* †	Tin, %	Lead, %	Antimony, % (Max.)	Melting Ranges			
				Solidus		Liquidus	
				°C	°F	°C	°F
70A	70	30	0.12	183	361	192	378

25C	25	73.7	1.5	184	364	263	504
20B	20	80	0.50	183	361	277	531
20C	20	79	1.2	184	364	270	517
15B	15	85	0.50	183	361	288	550
10B	10	90	0.50	183	361	299	570
5B	5	95	0.50	270	518	312	594

* For elements other than those mentioned in the table, the maximum content in the alloy shall be:

Bismuth	0.25%
Copper alloy grades 70A to 5B inclusive	0.08%
Iron	0.02%
Aluminum Zinc } each shall not exceed	0.005%

† The chemical requirements of SAE Specifications 1A, 2A, 2B, 3A, 3B, 4A, 4B, 5A, 5B, and 6A conform substantially to the requirements for alloy grades 45B, 40B, 40C, 30B, 30C, 25B, 25C, 20B, 20C, and 15B, respectively.

Because of wartime restrictions on the use of tin, substitute solders have been used for many applications. The most common substitutes are based on 15 to 20% tin, remainder lead, with and without the addition of various amounts of silver, antimony, bismuth, cadmium, and zinc. Substitute solders are reviewed by Rhines and Anderson * and Russell and Mack.† For outside seams and dry packs, the canning industry uses a lead-tin solder containing as low as 2% tin. Low-tin solders are more difficult to use because of the higher melting points, but industry has overcome the initial difficulties and little trouble is now experienced in their use.

SILVER SOLDERS, which contain a greater or less amount of silver together with varying quantities of copper and zinc, are used for brazing. Table 2 gives the composition and characteristics of silver solders covered by ASTM standard specifications, Designation B73-29. Grades 1 to 3 are suitable for brazing where a freer flowing solder than the ordinary copper-zinc brazing solders is required. Grades 4 and 5 will flow more freely at lower temperatures than grades 1 to 3. They are used where strong joints are required, and where the temperature necessary to flow grades 1 to 3 would injure the metal to which the solder is applied. Grades 6 to 8 are used where a high degree of malleability or ductility is required. (See also Section 21, Articles 6 to 9.)

SOLDERING FLUXES. Neutral fluxes such as rosin or rosin in alcohol are noncorrosive. They are used where corrosive action must be avoided and where removal of the flux residue is impractical. Their cleaning action is slight, and they are not suitable if the surface is oxidized. Activated rosin fluxes, containing a small amount of an organic compound, are now available. These activated rosin fluxes are much more efficient than rosin when soldering oxidized surfaces and are relatively noncorrosive. More active fluxes containing zinc chloride or ammonium chloride, or both, dissolved in water or mixed with petrolatum jelly, are manufactured and sold by several companies. The zinc chloride fluxes are corrosive, and the joints should be washed with weak muriatic acid (5 : 95) and then with water after soldering to remove the insoluble and hygroscopic residue of zinc oxychloride. A very active but corrosive flux suitable for soldering stainless steel contains zinc chloride, ammonium chloride, and stannic chloride with a small amount of hydrochloric acid. For silver solder and brazing alloys, powdered borax or the proprietary brazing fluxes are used.

HIGH-TEMPERATURE-RESISTANT ALLOYS

By C. T. Evans, Jr.

Materials used in high-temperature applications, particularly gas turbines, are currently the subject of intensive research and development. Table 1 lists the chemical compositions of selected old and new alloys employed for high-temperature applications in 1948. Other alloys still to be developed or whose compositions have not been published may ultimately replace some of these materials. The superalloys in the table are classified under three categories class A alloys, normally not heat treated; class B alloys, normally heat treated; class C alloys, fabricated by casting.

Two criteria of suitability for high-temperature high-stress applications are creep and stress rupture. The stress to produce a secondary creep rate of 1% in 10,000 hours is plotted in Fig. 1 against temperature. Ranges covered by superalloys of the three classes listed in Table 1 are compared with each other and with four typical older materials. Stresses to produce rupture in 1000 hours are plotted in Fig. 2. Corresponding data for the stress to produce creep and rupture in 100,000 hours are given in Figs. 3 and 4.

CARBON AND GRAPHITE

(Data furnished by National Carbon Co., Inc.)

Elemental carbon occurs in widely varied forms, from the transparent diamond with its extreme hardness to graphite which is gray and soft. Lampblack, charcoal, petroleum coke, and coal from which the volatile matter has been removed are nearly amorphous forms of carbon. Graphite is a crystalline form of carbon in which the atoms form a hexagonal pattern in a layer-like structure. Deposits of natural graphite are widely distributed. Large quantities have been found in Madagascar, Ceylon, and Mexico. Artificial graphite is prepared by heating certain forms of carbon, such as petroleum coke, to nearly 3000 C. In this temperature range, carbon assumes an orderly hexagonal crystal pattern similar to that of natural graphite. The transformation from carbon to graphite does not occur at a specific temperature but is a function of both time and temperature. Some forms of carbon, such as charcoal or lampblack, cannot be graphitized to the same degree as petroleum coke.

1. PHYSICAL PROPERTIES AND AVAILABLE FORMS

Carbon is chemically inactive, resisting the action of most acids (notably hydrofluoric), alkalies, and other chemicals, which are not highly oxidizing in their behavior. At incandescent temperatures, it does not melt, and the rate of oxidation is relatively slow. The thermal conductivity of carbon is high in comparison with most nonmetallic solid materials and, in graphitic form, exceeds that of many metals. This property, in combination with low coefficient of thermal expansion, gives to carbon products a very high resistance to thermal shock. Although much higher in electrical resistance than the metals, carbon is a good conductor of electricity and, for this reason, finds many applications in the electrical field and in allied industries. Physical properties of carbon are listed in Table 1, and specific heat is given in Fig. 1.

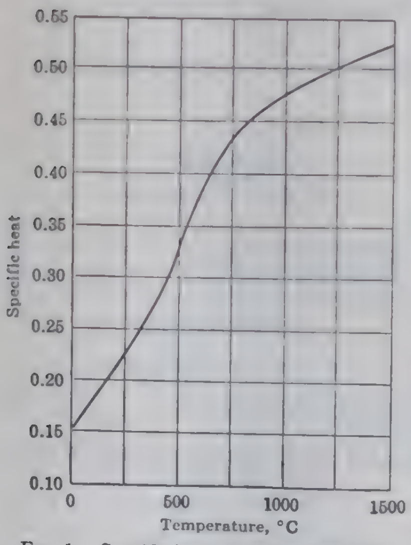

Fig. 1. Specific heat of carbon graphite.

FORMED CARBON. Formed carbon is usually prepared by mixing petroleum coke and/or coal or lampblack with pitch or tar and extruding or molding the mixture under pressure in the form of cylinders or blocks of various sizes. These shapes are baked on slow schedules to 700 to 1200 C to carbonize the binder and remove the volatile matter. The resultant product is a nearly amorphous material which is hard and strong and has a low electrical and thermal conductivity. (See Table 2.)

FORMED GRAPHITE. Formed graphite is prepared by mixing a graphitizable form of carbon, such as petroleum coke, with tar or pitch. This mixture is extruded or molded in the same manner as formed carbon, except that it is finally baked to temperatures near 3000 C in Acheson * resistance furnaces to graphitize the carbon. (See Table 2.)

IMPERVIOUS CARBON AND GRAPHITE (Karbate *) are carbon and graphite base materials impregnated with chemically resistant synthetic resins. The base materials are slightly permeable, but when resin is deposited in their pores they are rendered impervious to fluids under pressure and their strength is increased materially. Impregnation does not change the thermal conductivity of the base materials. By selection of the proper

† This property is also expressed as ohms/in.^{3} or ohms/cm.^{3}

type of resin impregnant, Karbate brand materials may be utilized in practically all chemical conditions in which the base materials are resistant. (See Table 2.)

LOW-TEMPERATURE OXIDATION OF CARBON AND GRAPHITE. Carbon and graphite are thermally stable and in reducing or nonoxidizing atmospheres will withstand temperatures up to 3600 C. In air the threshold oxidation temperature * is 400 C for commercial graphite and 350 C for carbon.

BRICK. Carbon and graphite corrosion-resistant brick are recommended for many types of construction where corrosive conditions or thermal shock are encountered. They resist the corrosive action of all acids, alkalies, and solvents except those of highly oxidizing character, adhere firmly to bonding materials, and are mechanically strong. (See Table 3.)

Graphite brick, although somewhat softer than carbon brick, possess the advantages of carbon brick plus a much higher thermal conductivity and greater resistance to oxidation.

Carbon and graphite brick and Karbate impervious brick are manufactured in practically all standard shapes, including scored and circle brick. Special shapes also can be provided. Carbon brick construction weighs approximately 100 lb per cu ft.

BEAMS, BLOCKS, PLATES, TILE, AND RODS. Carbon and graphite and impervious carbon and graphite are used in a variety of square, rectangular, round, and special sections, including beams, blocks, plates, tile, and rods. (See Table 4.)

Machined carbon beams are used as a material of construction where corrosive chemicals and severe thermal conditions are encountered. Installation of large beams is accomplished in a small fraction of the time required for standard brick construction. Premachining of parts also greatly simplifies assembly, with resultant savings in time and money.

Important uses of machined carbon beams are in electrostatic precipitators and supporting members in tanks, or vessels in chemical plants and paper mills.

TOWER PACKING. Carbon Raschig rings are suitable packing material for absorption, scrubbing, fractionation, and distillation towers. They are unaffected by acid, alkali, or organic conditions except those involving active oxidation. Because of their light weight and low thermal expansion, they are less susceptible to crushing, cracking, and spalling. (See Table 5.)

Other forms of carbon tower packing, such as tile, checker work, grills, and perforated plates, are also employed. Graphite and Karbate impervious graphite plates and bubble-caps are suitable for processes corrosive to the more common metals.

---

* The threshold oxidation temperature is defined as the temperature at which carbon or graphite undergoes a weight loss of less than 1% in 24 hours when exposed to air.

Note: Lineal expansion in percentage for temperature rise from

$$70\text{ F to temp } t\ (^\circ\text{F}) = \frac{a(t-70) + 0.00555(t-70)^2}{100{,}000}\ \%$$

$$21\text{ C to temp } t\ (^\circ\text{C}) = \frac{1.8a(t-21) + 0.018(t-21)^2}{100{,}000}\ \%$$

Porous carbon and porous graphite are chemically inert in practically all acids, alkalies, and organic compounds except those of strong oxidizing character. They are immune to thermal shock and are stable at all commercial temperatures in reducing atmospheres. Porous carbon starts to show significant oxidation in air at 660 F and porous graphite at 840 F.

Plates and tubes are particularly adaptable to the filtration of corrosive fluids and molten materials. A variety of forms and types of filters may be constructed. Porous carbon diffuser elements of several sizes and designs are used extensively in many chemical, physical, and biological reactions depending on the dispersion of a gas into a liquid.

2. APPLICATIONS OF CARBON AND GRAPHITE

HEAT EXCHANGERS. Shell- and tube-type exchangers, with heat transfer surfaces up to 700 sq ft per unit. The most common construction mounts Karbate (see p. 5-02) tube bundles in steel shells with metal baffle assemblies. Karbate head covers with standard connections are usually employed, but the covers may be made of other suitable materials. Where operating conditions require corrosion-resistant shells as well as tube bundles, all parts of the exchanger in contact with the corrosive fluids may be made of Karbate materials.

Plate-type heat exchangers, durable, compact units, resistant to thermal and mechanical shock, for heating or cooling pickling and plating solutions and other corrosive fluids; available in various styles ranging from 4 to 56 sq ft of heat transfer surface per unit.

Bayonet-type exchangers, conventional construction.

Sectional cascade coolers, constructed from prefabricated sections, 9 ft long, by sections stacked to form a series flow, vertical bank. Maximum cooling surfaces of approximately 360 sq ft are obtainable with any of the five pipe sizes—1, 1 1/2, 2, 3, and 4 in.

Jacketed pipe exchangers, with either metal or Karbate pipe jackets.

CONVEYING EQUIPMENT. Pipe and fittings, in twelve sizes from 1/2 in. through 10 in. Threaded, flanged, and flexible joints are available.

Globe valves, light in weight with short face-to-face dimensions. Corrosive fluids contact Karbate materials only.

Centrifugal pumps, open impeller type. All wet end parts are of corrosion-resistant Karbate material.

Jet pumps, Karbate impervious graphite parts for steam jet ejectors and injectors.

TOWERS. Tower sections and auxiliary parts such as support grills and distributor sections are available in sizes ranging from 8 in. ID to 33 in. ID. Complete towers are readily assembled from standard parts.

HYDROGEN CHLORIDE ABSORBERS. Standard absorbers complete with supporting structure and control equipment are available for gas concentrations ranging from 40 to 100% hydrogen chloride. Other types of absorbers are easily assembled from the standard line of Karbate equipment.

METALLURGICAL APPLICATIONS. Carbon (petroleum coke, anthracite coal, or lampblack base) and electric furnace graphite find many uses in the metallurgical field where materials are subjected to high and rapid changes in temperatures. The significant properties of carbon and graphite are given in Table 1. The materials are not attacked by, nor do they fuse with, slag. They are not "wet" by most metals, they do not warp at high temperature, and they have excellent resistance to heat spalling. Table 10 lists typical metallurgical applications.

Table 10. Metallurgical Applications for Carbon and Graphite

Application	Carbon	Graphite
Blast furnaces	Furnace linings Run-out trough linings Cinder notch cooler linings Cinder notch plugs	
Steel mills	Mold plugs	Mold stool inserts Molds for Jominy test bars
Steel foundries		Riser rods
Iron foundries	Core shapes Chill plates	Core shapes Chill plates

Variations in Dimensions of Carbon Electrodes. Dimensions are nominal. Variations permitted are: diameter or side, ±2%; length, +2 in.; curvature not to exceed 1/2% of length chord to arc. Ash: cylindrical, not more than 8 1/2%; square, 12%.

ELECTRODES. (See Tables 11 and 12.) In electrothermic applications, experience indicates that carbon electrodes operate to best advantage and give lowest costs in the production of carbide, abrasives, ferro alloys, and phosphorus. In these industries, carbon electrodes are used exclusively except in the production of some special grades of abrasives, ferro vanadium, and the very low carbon ferro alloys, where graphite electrodes are more satisfactory.

In the electric-furnace production of iron and steel, both types of electrodes are used, and the choice is based primarily on overall cost. Graphite electrodes cost about twice as much per pound as carbon, but the electrical conductivity of the former is approximately four times that of carbon of the same cross section. Consequently, a graphite electrode of about one-half the diameter of the carbon will carry the same current. In making a choice, however, the electrode cost is not always the governing factor, as power consumption, refractory costs, metallurgical conditions, freight, and many other items influence the final cost of the metal.

Variations in Dimensions of Graphite Materials. Dimensions are nominal. Average tolerances of unmachined materials are as follows:

Round: Under 2 1/2 in., ±2% of nominal diameter.
2 1/2 in., −1/16 in., +3/32 in.
Over 2 1/2 in., up to 6 in., ± 1/8 in.
6 in. and over, − 1/8 in., + 1/4 in.
Rectangular: ±2% of width and thickness.
Length: Less than 24 in., −1 1/2%, +2% of nominal length.
Over 24 in., −1/2%, +2%.
Curvature lengthwise, measured chord to arc, 1/2% of length.
Ash: Not more than 1 1/2%.

In electrolytic cells, anodes of graphite are preferable to carbon with but very few exceptions. The density, oxidation resistance, high purity, high electrical conductivity, and ease of machining and assembly are the characteristics which make graphite more useful and economical than carbon in this field.

In the electrolysis of aqueous or fused halogen salts, Acheson graphite anodes have met successfully the basic requirements of the ideal insoluble electrode as defined by high purity, good electrical conductivity, low halogen discharge potential and over-voltage, high mechanical strength, ease of machining and assembly, high resistance to anodic corrosion, and low initial cost.

Except for attack by nascent oxygen, at moderate temperatures graphite anodes are practically inert to all other chemical action. Consumption rate depends primarily on the degree of anodic oxygen generation; therefore, the extent to which oxidation can be controlled usually determines the relative cost for anodes in a particular application. Electrolytes containing sulfate, nitrate, or high concentrations of carbonate ions result in anodic discharge of oxygen, in turn leading to comparatively rapid anode disintegration. The limiting factor, therefore, in the economy of graphite as the anode material is the oxidation reaction rate and other related operating costs. When employed as cathode, graphite is not subject to oxidation and for this reason will show little or no deterioration in such service.

For electrochemical processes, Acheson graphite anodes are supplied in three grades: (1) regular quality, (2) "X" quality, and (3) special treated. The choice of these grades depends upon a number of different operating factors which vary with the type of electrolyzing equipment and the prevailing cost of power. Under what can ordinarily be called normal operating conditions, "X" quality will consume at a rate 15 to 20% less than regular quality and consequently is the choice in most processes where untreated anodes are employed. By reason of a higher apparent density, the "X" quality has approximately a 6% greater weight per piece than regular quality, but with the cost per pound the same the former has an operating cost advantage. Acheson special treated anodes under most comparable operating conditions will show consumption rates well below those for "X" quality; however, a slightly higher average cell voltage is usually encountered and must be considered in balancing increased power consumed against a saving in graphite cost.

CERAMICS

By Chester R. Austin

3. CHEMICAL STONEWARE

Chemical stoneware is made from a clay, or mixtures of clays, usually with a flux added. Proper proportioning of the raw materials permits ware of various properties, as desired, to be made. Chemical stoneware covers a range of ceramic products which at one extreme are as coarse in texture and as porous as firebrick and at the other extreme are as fine and dense as porcelain. The more porous bodies are more resistant to temperature changes; the denser ones are more resistant to corrosion. Chemical stoneware is used in places where resistance to acids, alkalies, and other chemicals is wanted. Concentrated and dilute materials of this nature, hot or cold, can be handled in chemical stoneware, with the

exceptions of hydrofluoric acid and strong caustic solutions. Severe temperature changes should not be permitted when chemical stoneware is employed.

In manufacturing chemical stoneware, selected raw clays and, usually, fluxes are made into a water suspension by blunging, screened, passed through a magnetic separator, and filtered to remove excess water. The filter press cakes are mixed, with any nonplastic ingredients to be added, in a wet pan. The mixes then are put through a pug mill or vacuum machine for final tempering. The mix is aged either after the mixing in the wet pan or after pugging to insure uniform moisture distribution and to improve the working properties of the mass. Machines are used to form brick, tower packings, stoppers, tile, and pipe. Piping is finished by hand. Other equipment is built entirely by hand by skilled workmen. Plaster molds are used to assist in forming certain pieces; others are made entirely without molds. Some pieces are made by casting a slip into plaster molds. After drying, the pieces are set in the kiln and fired to impart the desired properties. A salt glaze, formed by the reaction of salt, volatilized in the fireboxes, can be applied during the firing operation. Such a glaze improves the finish and appearance of certain ware. The fired ware frequently is machined with high-speed silicon carbide grinding wheels. Lapping and drilling with silicon carbide grain and cutting with diamond-impregnated blades also are employed.

Data on representative chemical stoneware bodies are given in Table 1.

4. STEATITE

Steatite is a generic term covering a class of ceramic products in which a preponderance of talc is used as a raw material. Oxides or compounds of the alkaline earths are added as fluxes. Clay is either entirely absent or present in small quantities, and an organic gum or plasticizer is added. Barium carbonate or other salt of barium is the most common flux used throughout the industry for production of a vitrified steatite body. Zircon or compounds of zircon are sometimes added to increase the thermal conductivity and decrease the thermal expansion. The ware is formed by machines and fired in ceramic kilns. The fired product is chiefly clinoenstatite ($MgO \cdot SiO_2$) crystals in a glassy matrix. Electrical loss properties of these bodies are controlled largely by the glass phase, whereas the other properties are controlled primarily by the crystal phases which are more or less constant for the entire family. A series of steatite bodies with different fluxes will not vary over 10 to 15% in their physical properties, but they may vary 3500% in volume resistivity at elevated temperatures.

Steatite bodies generally are prepared for fabrication by dry-process techniques in which the raw materials are blended thoroughly in a muller-type of mixer. In a few instances, the bodies are prepared by blunging or by kneading.

Steatite is formed by wet pressing, dry pressing, extruding, and casting. The method of fabrication depends on the shape, size, and purpose of the product. In the production of some items, secondary fabrication of the unburned ware is necessary, such as drilling, tapping, cutting, and machining; in other instances, the ware is ground or cut to size after burning.

Data on the properties of steatite are given in Table 2.

5. ELECTRICAL PORCELAIN

Electrical porcelain is a vitrified ceramic product produced from a mixture of clays, silica, and a flux or fluxes. Feldspar is the most common flux.

The general manufacturing procedures can be classified as wet process and dry process. The wet process is used for high-voltage purposes, and the dry process is employed for low-voltage insulation. The wet process can be subdivided into (1) plastic and (2) casting methods.

In wet-process porcelain, the raw materials are mixed thoroughly with water, usually in a blunger, to form a suspension, passed over screens and through a magnetic separator, and then filter pressed. For the cast method of wet process, the filter-press cakes are reblunged with water and electrolytes, and the resultant suspension, of thick-cream consistency, is ready for use. In the plastic wet-process method, the filter-press cakes usually are put through a de-airing machine before final forming.

In the dry process, the filter-press cakes may be dewatered by storage; the material is granulated in some type of pulverizer and screened, and then it is ready for final forming. An alternative method (dry mixing) is to start with a blending mixer, employ only fine

* These are average values obtained on unglazed porcelain in accordance with ASTM standard methods of testing, serial D116-42. See Notes 1, 2, and 3.

Note 1. The dielectric and mechanical strength values obtained from testing standard specimens are for general guidance only. The shape of specific designs, the nature of assembled metal parts, mechanical stresses, and other factors may have appreciable effect upon the strength of insulators. Design tests should, therefore, always be made definitely to establish breakdown values.

Note 2. Tensile strength is determined on a specimen designed to eliminate other forces, such as shearing. An increase in diameter of the test specimen results in a decrease in strength per unit area. This relationship is neither linear nor a simple curve. The test specimens used in obtaining the above average values for tensile strength were relatively large (1 1/8 in. diameter).

Note 3. Dielectric strength obtained on standard test specimens at 60 cycles under oil using 3/4-in. mercury sealed-in electrodes (ASTM method D116-42). Short-time tests: Voltage raised at rate of 0.5 kv/sec.

Note 4. In the assembly of porcelain bushings, studs, shells, etc., molten alloys and insulating compounds are often used. This work must be carried out very carefully to avoid cracking the porcelain. It is well to warm the porcelain to about 100 F before the operation and to avoid having the alloy or compound hotter than required for the proper fluidity for filling the joints.

Even slowly applied heat, if carried as high as 500 C, is very apt to leave the porcelain with substantially reduced mechanical strength.

* Porous refractory insulator bodies may have absorption of 10% or higher. They are special bodies to resist very rapid changes of temperature, as in electric ranges, rheostats, immersion heaters, and similar equipment.

† Power factor and dissipation factor are synonymous for values in the ranges cited.

‡ "Te" value is the temperature in °C at which the resistivity is 1 megohm per cm cube.

clays in the usual batch, and add the necessary amount of water. When discharged, the material is ready for final forming.

The wet-process plastic porcelain is shaped by being formed into approximately the desired shapes (blanks) and then dried to a certain extent. Final design is imparted by hand with spiral tools while the blank is revolved mechanically.

The wet-process cast porcelain is shaped by pouring the mix of thick-cream consistency into gypsum molds, which impart the desired shape; the water is absorbed sufficiently by the mold to enable the piece to be handled, and it then is removed from the mold. It may undergo further processes, such as trimming or grooving, before it is fired.

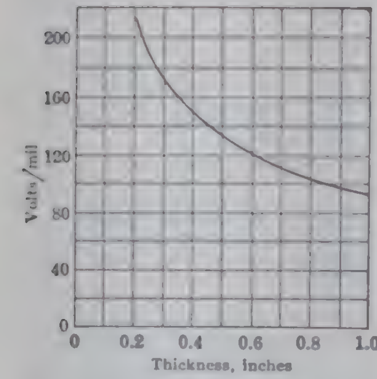

FIG. 1. Dielectric strength vs. thickness of unglazed, wet-process porcelain.

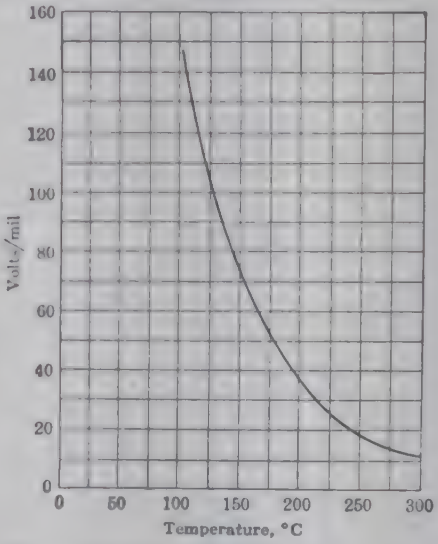

FIG. 2. Dielectric strength vs. temperature of unglazed wet-process porcelain. Tests made on a cylinder (wall thickness 0.136 in.) at 60 cycles in air, one minute step-by-step, using 1-in. lead-foil electrodes.

Dry-press porcelain is formed in steel dies by compressing the damp, coarse powder prepared by one of the two general methods described previously. Parts having lower porosity and higher dielectric strength can be made by pressing the mixture under vacuum.

After drying, pieces which require glazing are dipped or sprayed and are burned in ceramic kilns, usually at a temperature of about 2300 F.

Data on some specific electrical porcelain bodies and general ranges of properties are given in Tables 3 and 4.

6. BRICK AND TILE

BUILDING BRICK considered in this section are made from clay or shale and are fired after appropriate forming methods. The characteristics of the brick vary, depending on the particular clay and/or shale used, grinding, forming method, and burning treatment. In general, such brick are classified as face or common, depending on the intended application. Face brick are intended to be pleasing when exposed to view, and common brick most commonly are used for back-up purposes.

Building brick are made by grinding the raw clay and/or shale, tempering with water, in a pug mill or wet pan, and forming by machine. Extrusion is the most commonly employed method in which a solid column, extruded from an auger machine, is cut into appropriate sizes. Cores are used frequently in the extrusion machine to produce holes in the brick. Presses are also used. A few hand-molded brick are made. The brick then are dried and fired in ceramic kilns.

ASTM recognizes three classes of brick (ASTM C62-44):

SW—Brick intended for use where a high degree of resistance to frost action is desired and the exposure is such that the brick may be frozen when permeated with water. Brick used for foundation courses and retaining walls should conform to this grade. This grade is recommended for use where a high and uniform degree of resistance to weathering is desired.

MW—Brick intended for use where exposed to temperatures below freezing but unlikely to be permeated with water, or where a moderate and somewhat nonuniform resistance to frost is permissible. Brick used in the face of a wall above ground should conform to this grade. It should be emphasized that disintegration is not necessarily a characteristic of brick in this grade. They may, however, be a mixture of durable and nondurable brick. Examination of brick in this grade in the user's own territory after 10 to 20 years' service is the best method of making a selection.

NW—Brick intended for use as back-up or interior masonry, or, if exposed, for use where no frost action occurs; or if frost action occurs where the average annual precipitation is less than 20 in.

The physical requirements for brick to be classified in these grades are covered in ASTM specifications, the tests on which they are based being described in ASTM C67.

ASTM requires that the net cross-sectional area of the brick shall be at least 75% of the gross cross-sectional area (including holes) when measured in a plane parallel with the bearing surface of the brick. This limits the "coring" that may be used in fabrication.

In its report, *Recommended Minimum Requirements for Masonry Wall Construction* (1931), the Building Code Committee of the U. S. Department of Commerce recognizes four grades of brick according to compressive strength, tested flatwise: 1500–2500 psi; 2500–4500 psi; 4500–8000 psi; and over 8000 psi.

A standard size of brick is $2\frac{1}{4}$ by $3\frac{3}{4}$ by 8 in. Brick of this size, however, are not produced in all sections of United States.

STRUCTURAL CLAY TILE (ASTM C43-36) are hollow burned-clay masonry building units with parallel cells. They are made from fire clay, surface clay, shale, or mixtures of these materials. They are made by the same general procedure as building brick (clay or shale), but the forming is done by extrusion.

The American Society for Testing Materials (ASTM C34-41, C56-41, and C57-39) and the American Standards Association (ASA A74.1-1942, A76.1-1942, and A77.1-1942) recognize three general classifications of these products:

1. Structural Clay Load-bearing Wall Tile. *Grade LBX.* Suitable for general use in masonry construction and adapted for use in masonry exposed to weathering, provided they are burned to the normal maturity of the clay. They may also be considered suitable for the direct application of stucco.

Grade LB. Suitable for general use in masonry where not exposed to frost action, or for use in exposed masonry where protected with a facing of 3 in. or more of stone, brick, terra cotta, or other masonry.

The physical requirements of these tile and the requirements for the minimum number of cells in the direction of wall thickness and average weight are given in the standards referred to.

2. Structural Clay Non-load-bearing Tile. Partition, fireproofing, and furring tile are included in this group. Only one grade, NB, is recognized. The absorption requirements are given in the standards. Fireproofing tile intended for use in load-bearing masonry must have the same properties as structural clay load-bearing wall tile.

Partition and split furring tile requirements in regard to total number of cells, number of cells in the direction of wall thickness, and dry weights per square foot of tile are given in the standards. Requirements for minimum weights of structural clay non-load-bearing tile shall be waived if the overall thickness of the shells, measured between the inner and extreme outer surfaces, is not less than $\frac{5}{8}$ in. and the thickness of the webs is not less than $\frac{1}{2}$ in.

3. Structural Clay Floor Tile. [These tile are used as structural units in floor and roof construction.] Two grades are covered, designated Grade FT1 and Grade FT2. Both grades are suitable for use in flat or segmental arches or in combination tile and concrete ribbed-slab construction. Flat and segmental arch tile must meet the requirements for number of cells in the depth of the arch and average dry weights per square foot of tile. Tile designed to resist stresses in combination tile and concrete ribbed-slab construction should conform to the prescribed requirements as to number of cells in the direction of depth of slab, and average dry weights per square foot of tile. The requirements for minimum weights of structural clay floor tile may be waived if the overall thickness of the shells, measured between the inner and extreme outer surfaces, is not less than $\frac{5}{8}$ in. and the thickness of the webs is not less than $\frac{1}{2}$ in.

The standard methods for determining the physical requirements are given in ASTM C112-36 and ASA 83.1-1942.

Salt-glazed tile have a vitreous glaze on the surface produced by volatilizing salt in the kiln at the temperature used in finishing the burning.

In porous structural clay tile, the natural porosity of the clay or shale has been increased by the admixture of other ingredients.

DRAIN TILE (clay) are made from shale, fire clay, surface clay, or mixtures of these. The general procedure of manufacturing is about the same as for manufacturing structural clay tile. The extrusion machine, of course, always has a core to insure the proper wall thickness.

Three classes of drain tile are recognized by the American Society of Testing Materials (ASTM C4-24) and the American Standards Association (ASA A6-1925). These are:

1. **Farm drain tile,** for ordinary private drainage work on farms, for moderate sizes and depths.
2. **Standard drain tile,** for ordinary district land drainage at moderate depths.

3. **Extra-quality drain tile,** intended for district land drainage, for considerable depths and where an extra quality is desired.

In certain instances, freezing and thawing tests or special chemical requirements as to the resistance of the tile to chemical action in specific environments may be desirable. Visible grains or masses of caustic lime, iron pyrites, or any other minerals which are known to cause slaking or disintegration of the tile may be a valid ground for rejection unless satisfactory proof is afforded that the tile are permanent and durable.

CLAY SEWER PIPE * are made from surface clay, shale, fire clay, or a combination of these materials. The materials are formed into the desired shape and subjected to a suitable temperature for developing strength and density. The finished product is a composite of crystalline mineral grains bonded together with a glassy matrix. Because of its composition, it is dense, strong, and resistant to chemical attack. Because of the high degree of vitrification developed in the fired bodies, they commonly are referred to as vitrified clay pipe. They are used for domestic and municipal sewage disposal and for the handling of industrial waste and corrosive liquids.

In the manufacture of vitrified clay pipe, the raw material after mining is ground, screened, and mixed with the proper amount of water for forming. The prepared body is extruded through an annular die of the desired size and shape by one of several methods. After removal of the plasticizing water, the ware is fired in either periodic or continuous car tunnel kilns to a temperature suitable for developing the strength and absorption values desired. These temperatures vary between 1900 and 2100 F, depending on the refractoriness of the clays or shales.

Vitrified clay pipe usually are coated with a salt glaze which is applied during firing, or with a ceramic glaze which is applied before firing and is matured during the firing process. Some ware now are being made without any glaze coating.

Most pipe are made with the conventional socket joint which usually is filled with cement, asphalt, or coal-tar compounds. There are several prefabricated joints available for socket pipe. Ring pipe, cylindrical tubes without sockets, are produced principally in California where they are used widely with mechanical joints, which combine strength with some flexibility. A number of such joints are available.

Vitrified clay pipe are manufactured in two strength classifications identified as Standard and Extra Strength. They vary primarily in wall thickness and in the load which they are required to support. ASTM requirements are listed in ASTM C13-44T and C200-44T.

CORK

(Data furnished by Armstrong Cork Co.)

Cork is the spongy outer bark of the cork oak tree, which grows principally in Spain, Portugal, and northern Africa. It is of cellular structure, each cell comprising a strong, impenetrable skin, enclosing air.

NATURAL CORK. The uses of natural cork are limited by the variability of the raw material, by structural flaws, which are uncontrollable in a natural material, and by the irregularity in size, thickness, and shape. These limitations can be overcome by laminating the corkwood to produce a material of greater uniformity and structural strength.

CORK COMPOSITIONS. Finely ground cork combined with various binders form materials having all the desirable basic qualities of natural cork. Composition can be made to provide for expansion or contraction, and to be fabricated into sheets, disks, tubes, blocks, rings, strips, balls, wheels, rods, and irregularly shaped articles. Composition is laminated with cloth, vulcanized fiber, or other material to increase the tensile strength.

Cork and rubber compositions are employed for applications where certain properties of the various synthetic or natural rubbers are required but where their normal side flow under compression is objectionable. By combining compressible cork particles with noncompressible rubbers, there results a group of compositions in which side flow is either reduced to a specified value or virtually eliminated.

PROPERTIES OF CORK. Resistance to Liquid Penetration. Cork is highly resistant to penetration by liquids. Since it is not fibrous, liquids are not drawn through it by capillary action.

---

* Data from Dr. J. O. Everhart, Engineering Experiment Station, Ohio State University, Columbus, Ohio.

Compressibility. Cork is truly compressible, undergoing actual reduction of volume when compressed. This property is often referred to as compressibility without side flow, inasmuch as Poisson's ratio is virtually zero.

Resilience. Long subjection to pressure does not destroy the structure or resilience of cork. It will not harden nor deteriorate under normal conditions.

Buoyancy. Natural cork, after removal of the outer layer of "hardback," has a specific gravity of 0.15 to 0.20 and in this form is used for floats or other devices requiring buoyancy.

Thermal Conductivity. The air-cell structure of cork forms an excellent insulator. It is highly resistant to charring and ignition. At about 250 F, slow distillation begins and the cork discolors slightly. It does not ignite except in contact with flame, and it burns only as long as flame is applied from an external source. Combustion produces a carbonized coating which retards further burning.

Chemical Inertness. Cork resists chemical action better than most natural materials and can be safely used in contact with most chemicals. In industrial processes it does not corrode, discolor, or deteriorate and is not affected by oil, grease, gasoline, or other petroleum products. Alkalis, certain acids, and a few organic solvents have destructive action; as a rule, cork should not be used in contact with them. Iron solutions sometimes react with the natural tannin in the cork to cause the surface discoloration, which does not affect the properties of the cork.

Stability. Cork retains its initial properties practically unimpaired under widely varying conditions of temperature, humidity, or other atmospheric conditions. Its compressibility and resilience enable it to withstand abrasive wear. It is not subject to progressive deterioration with age.

Friction Properties. Owing apparently to the fact that the cell structure presents a myriad of minute vacuum cups, the coefficient of friction of natural cork and compositions is higher than that of most materials used for friction. This property is not materially decreased by the presence of moisture or oil. Operating temperatures are the principal limiting factor, as cork does not stand sustained high temperatures in excess of 250 F, although it may successfully withstand surges to 300 or even 350 F. This factor tends to limit its use to light-duty applications or to heavy-duty designs involving little slippage. However, if special means of heat dissipation are provided, clutches involving a comparatively high amount of intentional slippage may successfully use cork facings. Thus, designers of oil-filled clutches and torque converters for automobiles have taken advantage of cork's ability to retain a high coefficient of friction in oil, while the presence of the oil avoids the build-up of frictional heat which would be damaging to the cork.

Compositions are used more extensively than natural cork for reasons of uniformity and control of compressibility and other properties. In practice, laboratory data have defied translation into actual performance data, and the "cut-and-try" method of evaluation is strongly recommended. As a starting point in design calculations, a coefficient of friction of 0.5 is suggested for dry assemblies involving quick starts or stops; 0.25 is suggested for oil-filled devices.

USES. Following are the principal applications of cork and cork products:

Gaskets and Packings. Cork gaskets are widely used in many types of machines and devices for sealing liquids such as water, gasoline, oil, etc., and for cushioning between adjoining surfaces of metal and glass or similar combinations. The compressibility and resilience of cork permit a seal even when the adjoining surfaces are comparatively rough and irregular.

Insulation (Thermal). Cork and cork compositions find wide application as insulation for refrigerating equipment and in cold-storage plants, ships, cars, trucks, etc. See Heat Insulation in *Power* Volume, Kent's *Mechanical Engineers' Handbook*. Special parts also are made in the form of handles for industrial equipment where heat insulation is required.

Insulation (Noise and Vibration). Cork and cork compositions are used as resilient cushions under machines to isolate them from their surroundings. They are also used in the form of panels for sound deadening of walls, to reduce reflection of sound waves back into a room. See Section 9, Vibration and Noise Control.

Friction. Applications include clutch facings, friction wheels, feed rolls, high-friction grips for fishing rods, tools, and instruments.

Floats. Applications include gage mechanisms, carburetors, dispensing pumps for oil and gasoline, and life preservers.

FELT

By William H. Lehmberg

Felt is one of the most versatile nonmetallic materials employed for mechanical purposes. Its adaptable range of densities from soft to hard and the fact that it is resilient, durable, and will not ravel when cut are among the properties responsible for its extensive use.

DEFINITION. Felt is a fabric built up by the interlocking of fibers by a suitable combination of mechanical work, chemical action, moisture, and heat, without spinning, weaving, or knitting. It may consist of one or more classes of fibers; wool, reprocessed wool, and/or reused wool; with or without admixture with animal, vegetable, and synthetic fibers.

MANUFACTURE. Processes in the manufacture of felt follow the general pattern of wool-textile manufacture except for two distinct operations, hardening and fulling, which replace conventional spinning and weaving. Processes in order of sequence include: fiber blending and picking, carding, hardening, fulling, scouring and neutralizing, dyeing, drying, sanding and/or shearing, and press finishing. Cross laying of carded webs is employed to develop balanced strength in lengthwise and widthwise directions. The amount of felting (hardening and fulling), in combination with selective fiber blending, governs felt density and the performance characteristics of the finished felt.

MECHANICAL FELT STANDARDS AND SPECIFICATIONS. Mechanical felt standards and specifications apply to (1) roll felts, which, depending on type and density, are customarily fabricated in 15- to 30-yd lengths, 3/64 to 1 in. thick, 60 or 72 in. wide; and (2) sheet felts, which are customarily made in 36-in. squares, 1/8 to 3 in. thick. Specification conformance tests are governed by ASTM D461, *Standard Methods of Testing Felt.*

Roll Felt Specifications. Specifications covering standard types of roll felt for automotive, aircraft, and other mechanical uses are given in Table 5. SAE, ASTM, and Felt Association type number designations are listed.

Sheet Felt Specifications. Standard types of sheet felt including weight and thickness specifications were established by the Felt Association in September 1948. (See Table 6.) These specifications cover all standard sheet felt types, thicknesses, and densities for mechanical use and apply only to those felts which are manufactured in individual sheets rather than in roll or yardage form.

PROPERTIES OF FELT. Depending on the purposes they are designed to serve, felts differ in density, fiber blend, and construction. Distinctions between these characteristics largely distinguish the performance of one type or grade from another. Engineering data typifying the general behavior of mechanical felts in several fields of application and under various working conditions are given in the following paragraphs. These data have been established from test results made available by the Felt Association, and, although they do not constitute specification material, they provide a general guide to the selection of standard grades for mechanical purposes.

Formability. Felt is particularly suited to form shaping by stretching or molding. In tension, it develops a progressive reaction to increased loading which results in a high rate of elongation before rupture.

Compressibility and Resilience. Load deflection and compression set values for standard mechanical roll felts are given in Tables 1 and 2. Wool felts are characteristically resilient, will not crumble or flow, and do not deteriorate with age. Load deflections up to 30% produce less than 5% permanent deformation. The high degree of compressibility and resilience of the lower-density felts makes them ideally adaptable to cushioning, form sealing, packing, padding, and damping.

Table 1. Load Deflection of SAE Felts *

Load, psi	Deformation, %					
	F-1	F-3	F-5	F-10	F-11	F-15
10	5	8	15	30	25	30
20	9	14	22	39	33	37
40	17	21	30	46	42	45
60	23	25	35	50	47	49
80	26	29	39	54	51	53
100	29	31	41	56	54	55
200	37	39	49	62	61	62
400	47	49	58	71	69	70

* Deformation reported is the percentage of decrease in original measured thickness 1 min after loading to the nominal compressive stress.

Table 2. Compression Set of SAE Felts *

Load Deflection, %	F-1		F-3		F-5		F-10		F-11		F-15	
	Load, psi	Comp. Set, %	Load, psi	Comp. Set, %	Load, psi	Comp. Set, %	Load, psi	Comp. Set, %	Load, psi	Comp. Set, %	Load, psi	Comp. Set, %
10	21	1	13	1	6	1	4	1	4	1	3	1
20	45	2	35	3	17	2	7	2	7	2	6	2
30	108	4	93	6	41	4	9	3	15	4	10	4
40	246	7	210	9	91	6	24	6	34	6	26	6

* Compression set reported is the percentage of difference between original and final felt thickness as determined by loading for 1 min to the stated deformation and measuring final thickness 1 min after unloading for recovery.

Frictional Properties. The coefficient of friction of felt is largely independent of density and type and averages approximately 0.22 for dry felt against steel. The frictional force developed by felt, however, depends on the texture and smoothness of adjacent surfaces as well as on the viscosity and character of associated lubricating oils and greases or other liquids. Coefficients of static friction of felt against smooth, clean surfaces of wood and glass average 0.37 and 0.26, respectively. Against steel lightly lubricated with SAE 30 aviation oil, the coefficient of friction of felt is 0.18.

Wear Resistance. The wear resistance of felt varies in direct proportion to density and fiber quality and in inverse proportion to applied load. The excellent wear resistance of high-density roll and sheet felts is one of their most important properties. Fabricated into laps, wheels, and bobs, these felts are used extensively for polishing optical and ophthalmic lenses, plate glass, plastics, and metals. Others are similarly employed for the continuous wiping of brass and steel in sheet and strip mills.

Sound Absorption and Thermal Insulation. Owing to its structure, felt is a highly efficient sound-absorbing and thermal-insulating material. It is easy to handle, will not disintegrate from vibration, and will not collapse when wet. Thermal conductivity decreases with decreased felt density, and many of the lighter weight mechanical grades have *K* factors of less than 0.25. See Table 3. Combinations of kapok fiber with wool produce felts of 0.21 *K* factor and of 0.80 sound absorption coefficient at frequencies above 512 cps. These felts weigh approximately 3.2 lb per sq yd for 1 in. thickness and are designed specially for military and commercial aircraft insulation. Kapok felts as well as standard mechanical types are applied industrially at temperatures up to 200 F to insulate process equipment and instruments, reduce general noise level, soundproof test rooms and ventilating ducts, and dampen noise generated by machine vibration. For most applications, sound and thermal insulating felts are proofed for resistance to flame, fungi, mildew, moth, and vermin.

Table 3. Thermal Conductivity of SAE Felts *

	Btu/Hr/Sq Ft/°F				
	F-1	F-3	F-5	F-11	F-15
K Factor, 1-in. thickness	0.36	0.35	0.30	0.23	0.24

* Thermal insulation felts blended with kapok fiber have tested values of 0.21 *K* factor.

Absorption Capacity and Capillarity. Foremost among the important functional properties of felt is its ability to absorb, store, or feed oil and grease in mechanical sealing,

(Continued on p. 5-24)

Table 4. Percentage of Oil Absorption Capacity of SAE Felts *

	Viscosity, Saybolt Universal Seconds at 70 F

* Splitting resistance is not applicable to felts where the thickness is less than 3/16 in. For materials less than 3/16 in. in thickness, breaking strength only is recommended as an indicative test.

† For thicknesses under 1/8 in., see F-50.

‡ For thicknesses under 1/8 in., see F-51.

§ For thicknesses under 1/8 in., see F-55.

‖ The wool content indicates the percentage of wool by chemical analysis, but does not differentiate between wool, reprocessed wool, and reused wool, and is exclusive of traces of other fibers and impurities present in the wool used in fabricating the several types of felt. For example, Type 16R1, fabricated from 100% wool, may contain incidental traces of other fibers, residual wool fats, and oils or soaps used in processing which may reduce the actual wool fiber content on analysis to a minimum of 95%.

* Made in sheets 36 by 36 in.

† Sheets of $1/8$-in. thickness are manufactured on order in Nos. 20-S, 26-S, and 32-S.

lubricating, and wicking applications. Absorption or storage capacity is principally a function of felt density, increasing in direct inverse proportion to density as shown in Table 4. The capillarity of felt, or distance to which felt will wick liquids, increases with felt density but varies in inverse proportion to fluid viscosity. For design purposes, delivery rates can be estimated from the following formula derived from experimental test data:

$$Q = \frac{0.8 \times 60DCAR}{G}$$

where Q = delivery rate, cubic centimeters per hour.
0.8 = average coefficient of capillarity.
D = density of felt, grams per cubic inch

$$= \frac{\text{per cent specific gravity}}{100} \times 16.4.$$

C = absorption capacity of felt, percentage.
A = cross-sectional area of wick, square inches.
R = wick-rise rate, inches per minute at specified wicking distance.
G = specific gravity of fluid.
60 = conversion from cubic centimeters per minute to cubic centimeters per hour.

Chemical Inertness. The effects of distilled, tap, chlorinated, or sea water on the physical properties of felt after extended immersion at 70 F and 212 F are moderate thickness swell, slight dimensional shrinkage in length and width, increased rate of elongation under tensile stress, and decreased wet breaking strength to the extent of about 25%. Felts may be treated for water repellency and when treated will demonstrate improved stability.

Extended exposure of felt to lubricating oils, greases, and organic solvents has no appreciable effect on the dimensional stability or physical properties of felt. Strong inorganic acids are noninjurious in concentrations up to 14 Bé. Nitric acid in 14 Bé concentration, however, reduces the breaking strength of wool felt by 30 to 40% after 5-day immersion. Strong bases or alkalis are injurious.

Felt, unlike many organic substances, may be considered a nonaging material. The natural destructive forces of atmospheric temperature, ozone, and ultraviolet radiation are essentially nonreactive. Felt is unchanged by increased temperatures up to 212 F. Above 212 F, wool loses its hygroscopic moisture and becomes harsh to the touch, and the physical properties of breaking strength, elongation, and splitting resistance are adversely affected. At low temperatures, felt is the same at −60 F, in the absence of condensate, as at normal room temperatures. At −80 F, its properties are only slightly different.

Mechanical Felt Applications. There are, as a minimum, fifteen important mechanical functions fulfilled by felt, i.e., sealing, wicking, wiping, polishing, vibration isolation, filtration, sound absorption, thermal insulation, shock absorption, cushioning, dampening, padding, packaging, surfacing, and frictional applications.

Precision-cut washers, fabricated from felt or felt laminated with oil resistant synthetic elastomers, seal against loss of lubricant and protect ball and antifriction bearings from dirt, grit, and moisture. Felt filters for industrial respirators, air-conditioning units, process and product filters, including pigments, paint, lacquer, photographic emulsions, and food syrups, are highly retentive, permeable, and characteristically slow plugging. Vibration mountings for machines, weather stripping, automotive window channels, antisqueak body spacers, polishing wheels, and laps are other typical felt applications, as are wicks for motor-bearing lubrication, sound insulation for commercial and military aircraft, and nonskid scratch protection for fan bases, instruments, and furniture.

TYPICAL MECHANICAL ROLL FELT APPLICATIONS. Type 18R1 is recommended where unusual strength and hardness are required. Typical uses include: small-diameter wicks, polishing wheels, blocks and pads, bumpers, grommets, and precision washers.

Type 16R1 (SAE F-1) is suitable for oil retention in installations where the felt is not compressed or for feeding low viscosity or light oil. Typical uses are: washers; bushings; wicks; door bumpers; polishing blocks, wheels, and pads; grommets; window channels; resilient mountings, antivibration and dampening pads; and parts where wear and resistance to abrasion are required.

Types 16R2 (SAE F-2) and 16R3 (SAE F-3) are recommended for vibration mountings and oil and grease shields, and for the same general purposes as SAE F-1 but where a felt of slightly lower tenacity is satisfactory.

Types 12R1 (SAE F-5), 12R2 (SAE F-6), and 12R3 (SAE F-7) are recommended for dust shields, wipers, grease retainer washers, wicks, vibration mountings, and where a resilient felt is required.

Types 9R1 (SAE F-10), 9R2 (SAE F-11), and 9R3 (SAE F-12) are recommended for grease and oil retention where the felt is confined and compressed in assembly. They are also recommended for dust shields under less severe operating conditions, where 12R1, 12R2, and 12R3 are not required.

Types 9R4 (SAE F-13) and 9R5 (SAE F-15) are recommended for sound deadening, chassis strips, spacers, dust shields, pedal pads, and dash liners, and for mechanical purposes where abrasion and wear are not important factors.

Type 8R5 (SAE F-26) is suitable for packing or padding when held in place between other materials. This grade should not be used for mechanical purposes.

Type 16RX1 (SAE F-50) is recommended for ball- and roller-bearing oil retainer washers, and small dust-excluding washers, and for mechanical purposes where an accurate, thin, smooth high grade felt is required.

Type 16RX3 (SAE F-51) is recommended for the same general uses as F-50 but in installations where tolerances and length of life are not so important. It is also used for thin cut parts such as gaskets and liners.

Type 12RX3 (SAE F-55) is recommended for antisqueak strips and for lining when cemented to fiber board or metal panels.

TYPICAL SHEET FELT APPLICATIONS. Types 12S1 to 12S4, depending on fiber fineness required, are suitable as absorbent pads, vibration and shock mountings, and dampeners, and for fine and soft metal polishing, buffs, and the like.

Types 16S1 to 16S4 are suitable for the same general uses as 12S1 to 12S4 where a slightly denser felt is required, as well as for oil and fluid wicks, washers, plugs, bushings, channels, bumpers, ink and fluid transfer rolls, and general-purpose polishing blocks.

Types 20S1 to 20S4, depending on fineness requirements, are recommended for mirror and glass polishing, lens polishing, cash carrier heads, bumpers, ink rolls, rubber stamp pads, shoe insoles, scratch wheels, wood polishing, furniture rubbing, and punched wicks.

Types 26S1 to 26S4, depending on fineness requirements, are recommended for glass tumbler polishing, marble and granite polishing, artificial limbs, furniture casters, shoe and boot soles, block cutters, and for the same general uses as 20S1 to 20S4 where a denser felt is required.

Types 32S1 to 32S4 are used for heavy-duty grinding and polishing wheels as well as for the same general purposes as 26S1 to 26S4 where a dense quality is needed.

GLASS

By Harold G. Vogt

7. DEFINITION AND CHEMICAL NATURE OF GLASS

Glass is an inorganic product of fusion which has been cooled to a rigid condition without crystallizing (ASTM C162-45T). It is typically hard and breaks with conchoidal fracture. Although basically homogeneous and transparent, masses or bodies of glass may be made colored, translucent, or opaque by the inclusion of dissolved, amorphous, or crystalline materials.

Glass is made by heating a mixture of dry, powdered, or granular ingredients at about 2800 F in a refractory container until a viscous, homogeneous liquid is formed. The batch consists of the following raw materials in the form of oxides or of compounds which yield such oxides: (1) almost always silica (sand) as the glass former, (2) usually some lime and soda ash for fluxing, and (3) often one or more of the following for modifying purposes: potash, lead oxide, boron oxide, alumina, magnesia, barium oxide, and zinc oxide. Small pieces of scrap glass, "cullet," from a previous melt are usually added and, depending upon many special circumstances, the batch may include small amounts of one or more oxidizing, decolorizing, coloring, or opacifying agents.

The proportions of the raw materials in the batch very seldom correspond to those of chemical compounds. The proportions may be varied continuously over relatively wide ranges; some of the physical and chemical properties of the resulting glasses vary continuously over wide ranges, some remain practically constant, and others vary over small ranges. Also, there is considerable choice as to which and how many ingredients are to be used. Through a study of the properties of some 50,000 glasses, it has been possible to select the formulas that are best fitted for specific applications. About 400 different glasses, which differ considerably in some of their properties, are melted commercially each year. Of these glasses, a relatively small number have such general usefulness that they are melted continuously and in great volume.

TYPES OF GLASSES. The great bulk of commercial production is commonly classified in the following chemical types of silicate glass, listed in order of decreasing costs, decreasing softening temperatures, decreasing thermal shock resistances, and increasing thermal expansion coefficients. (1) 99.8% silica glass, i.e. fused quartz or fused silica, (2) 96% silica glasses, (3) borosilicate glasses, (4) lead glasses, and (5) soda-lime glasses. The commercial ranges in compositions of these types, as determined by analysis and calculation of oxide equivalents of the finished glasses, are given in Table 1, and the physical properties of some typical representatives of each type are given in Table 2.

Table 1. Composition Ranges of Commercial Glasses

Oxide	Soda Lime	Lead	Borosilicate	96% Silica	Fused Quartz
SiO_2	70–75%	53–67%	73–82%	96%	99.8%
Na_2O	12–18	5–10	3–10	....	......
K_2O	0–1	1–10	0.4–1	....	......
CaO	5–14	0–6	0–1	....	......
PbO	....	20–40	0–10	....	......
B_2O_3	....	....	5–20	3+	.....
Al_2O_3	0.5–1.5	....	2–3	....	......
MgO	0–4	....	....	....	......

In other types of glasses, such as colored, opal, and optical, the chemical composition is not the distinguishing characteristic. Such glasses are usually made from the foregoing types or "hybrids" thereof. Colored glasses are made by adding traces generally of metallic oxides to the batch, plus proper heat treatment of the finished glass where needed. Opal glasses most often are made by adding fluorides or phosphates to the batch, and the finished glass is treated so that small particles appear in the body of otherwise transparent glass and cause the scattering light that makes opal glasses appear "milky." Optical glasses are made from a variety of compositions to get desired combinations of index of refraction and dispersive constant. Their distinguishing characteristic lies in the stringent degree of freedom from physical imperfections required in the finished glasses.

There are some nonsilicate glasses, e.g., borate and phosphate glasses, made in small quantities for special uses.

8. PHYSICAL AND CHEMICAL PROPERTIES

During recent decades, industrial users of glass have adopted much more of an engineering approach toward its application, and glassmakers, through intensive research, have acquired scientific understanding and technical control of the material. New, superior, chemical types have been developed, particularly the low-expansion borosilicate glasses and 96% silica glasses. Technological improvements have been made in the old soda-lime and lead types, and designing and finishing treatments have advanced greatly. The resulting improvements in mechanical strength, thermal endurance, chemical durability, and electrical properties have been so marked that glass, particularly of the low-expansion types, has gained wide recognition as a versatile engineering material.

Despite the fact that relatively low tensile strength and limitations on cold working are disadvantages for many engineering uses, the toughness of most glass products today is such that the lay term, "brittleness," associated with the products of a few decades ago, is inappropriate. Modern glass is turning out to be strong enough for a great number and variety of new industrial uses. Its unique and excellent combinations of physical and chemical properties are great advantages. Some of its fine characteristics are:

1. Transparency—very high and permanent. Translucency or opaqueness can be obtained as desired, also versatile control over differential transmission or blocking of infrared, visible, or ultraviolet light.
2. Smoothness of molded surfaces or supersmoothness of ground and polished surfaces.
3. Great resistance to the attack of chemicals except hydrofluoric acid, i.e., superlative corrosion resistance. Correlated with this is the freedom from contamination of materials in contact with it.
4. Good hardness and resistance to scratching.
5. Dimensional stability or permanence of shape better than that of concrete or steel (hence the use of glass for the 20-ton, 200-in. mirror disk for the Mount Palomar Observatory telescope). Glass is free from creep, from elastic hysteresis, and from liability to permanent deformation under thermal or mechanical stresses that do not exceed breaking values.
6. Lightness or low specific gravity.
7. Low heat conductivity.
8. Good-to-excellent resistance to heat.
9. Very low expansion coefficients available in borosilicates or 96% silica glasses.
10. Good resistance to thermal stresses of the low-expansion types.
11. Small coefficient of reflection for radiant heat. Baking dishes of glass, despite their lower heat conductivity, bake their contents faster than do shiny metal dishes.
12. Excellent electrical insulation and dielectric properties.
13. Ease of hot-forming intricate shapes.
14. Wide range of fine, permanent colors.

Table 2. Physical Properties of Some Typical Glasses *

	Specific Gravity	Tensile Strength (annealed samples), 10^3 psi	Modulus of Elasticity, 10^6 psi	Linear Thermal Expansion Coefficient, 10^{-5} cm/cm/°C	"Softening" Point °F	Annealing Point, °F	Strain Point, °F	Thermal Conductivity, 10^{-4} g-cal/sec/cm^2/(°C/cm)	Specific Heat, g-cal/g/°C	Volume Resistivity (annealed samples), ohm-cm	Dielectric Constant, at 1 megacycle	Dielectric Power Factor, %, at 1 megacycle	Dielectric Strength, volts/mil at 60 cps	Refractive Index, for sodium D line

* Use in conjunction with general remarks in text on properties.

† For safe design practice, tensile stresses should not exceed 1000 psi for annealed glass, 2000 to 4000 psi for tempered glass, depending on piece.

‡ Approximate values.

In applying the specific values for various properties of glass listed in Table 2, it is necessary to keep in mind the following general comments because the physical nature of glass is so different from that of other engineering materials.

MECHANICAL PROPERTIES. Glass is a supercooled liquid and is not crystalline or endowed with any directional properties as crystals are. It is nonductile and perfectly elastic, i.e., it shows no cold flow, up to the point of stress necessary to break it. It seems to be broken only by tensile stresses, the fracture starting in almost all cases from imperfections in the surface. Glass does not deform or decompose with aging or exposure to moisture, and it suffers no permanent deformation when subjected to mechanical or thermal stresses, even at very low or quite high temperatures. Having no porosity, it does not swell or shrink with changes of humidity or immersion.

Strength. For safe design practice, tensile stresses should be limited to 1000 psi maximum for annealed articles and to 2000 psi for tempered articles of glass. This is true since, although annealed articles have tensile strengths ranging from 4000 to 10,000 psi and although many products can be tempered to have two to five times the strengths of annealed products, the evaluation of safety factors is rather difficult and depends on the type of application and the condition of the surface.

The nature of the surface has a great effect on the tensile strength of glass. Not only are loading stresses considerably magnified in regions of surface imperfections, e.g., scratches, but also the stress concentrations cannot be relieved by any yielding or cold flow since glass is nonductile. Consequently, the strength of most glass articles is markedly less than the 500,000 psi and upwards found with some fibers of glass. There are also noticeable variations in the measured strengths. Tempering puts a permanent compressive stress in the surface and thereby strengthens a glass article and makes the glass more resistant to abrasion and scratching.

Glass tested in compression or shear seems always to be broken by the tension components of stress, and the terms compressive strength and shear strength are generally considered to have little meaning for glass. However, the apparent or effective compression strength is about ten times as great as the normally measured tensile strength, and consequently it is a decided advantage, when glass is used in conjunction with metals or other materials, to plan the design so that forces on the glass are compressive rather than tensile. This is particularly true when temperature changes may introduce considerable stress in the glass because of differences in expansion coefficients.

Modulus of Elasticity. Young's modulus ranges from 6.5×10^6 to 12×10^6 psi for the various glasses. Poisson's ratio ranges from 0.18 to 0.30, but 0.22 may safely be used in calculations.

Hardness. The nonductility of glass makes it difficult to assess the significance of indentation tests, and glass manufacturers use tests different from those used for metals. On the Moh scale of resistance to scratching, where diamond is arbitrarily assigned a figure of 10, glasses range from 5 to 7.

The terms hard and soft as used in the glass trade seldom refer to the mechanical hardness but rather to the question of whether a glass has a high or low softening temperature.

THERMAL PROPERTIES. Reference Temperatures and Maximum Operating Temperature. Consonant with the fact that glass is a supercooled liquid, it has no critical temperatures. It has no freezing or melting point, and the viscosity changes continuously with change of temperature. The "melting temperature" of glass is merely a high temperature at which the batch of materials will fuse together and give a homogeneous, viscous liquid in a reasonable length of time. The viscosities of glasses are about 100 poises, even at the melting temperatures. For practical control of shaping and annealing operations, certain useful reference temperatures have been defined. The softening, annealing, and strain points are the temperatures at which glasses have more or less closely the viscosities of 4.5×10^7, 2.5×10^{13}, and 4.0×10^{14} poises, respectively. At the annealing point, the upper end of the annealing temperature range, internal stresses are substantially relieved in 15 min, whereas at the strain point temperature, the lower end of the annealing range, it takes 16 hr. In cooling through the strain point temperature, the properties have already begun to lag appreciably behind the temperature, and thus the viscosity reached in annealing practice may be appreciably greater or less than 4.0×10^{14} poises, depending on the speed of cooling. It is for these reasons that the *maximum operating temperature* for annealed ware, if undue thermal shock is avoided, may approach the strain point with no danger of introducing appreciable permanent strain, but for tempered ware it must be lower in order not to decrease the greater strength achieved by tempering.

Linear Thermal Expansion Coefficients. Coefficients of glasses range from values equal to those of metals to values one-thirtieth those of metals. The values tabulated are averages for the temperature range 0 to 300 C, but they differ little from the values for the range 20 to 80 C.

Thermal conductivity at room temperature ranges from 0.0018 to 0.0033 g-cal/sec/cm^2/(°C cm) for different glasses. For a typical borosilicate glass, the value at 250 C is 20 to 25% higher than at room temperature.

Thermal endurance is the ability to withstand, without cracking or breaking, rapid or uneven changes of temperature of the glass. Since thermal endurance depends on all those complicated factors controlling tensile strength and on other factors, no general formula has been found for glass articles. There are, however, several useful generalizations. (1) The smaller the coefficient of expansion, the greater the thermal endurance. (2) The thicker the glass, the more apt it is to break from thermal shock. (3) Glass will stand a much greater total immersion thermal shock when heated than when cooled since in heating the surface is put into compression whereas in cooling the surface is put into tension. Ordinary bottles are made of soda-lime glass and will usually break if plunged from boiling water into ice water, but articles of the low-expansion borosilicate glasses usually will not crack even with a wall thickness up to 1/2 in. The 96% silica glasses do not break even if plunged into ice water while they are at a glowing red heat.

ELECTRICAL PROPERTIES. Resistivity. The very high values of resistivity of most glasses make it difficult to obtain reliable data at room temperature. Volume resistivities of annealed glasses at 20 C range from 10^8 to 10^{18} ohm-cm, but generally they are 10^{12} ohm-cm or higher.

Dielectric Strength. The dielectric strengths of glasses in air range from 1000 to 8000 volts per mil of thickness and are so high that measurements often are made under dry oil to prevent "flashover." Under these conditions, the oil generally fails first and sets up point electric stresses of extreme magnitude, with the result that only a fraction of the true dielectric strength of glass is measured. Consequently, data taken under oil should be used only when the insulator is intended for service under oil.

CORROSION RESISTANCE AND CHEMICAL DURABILITY. One of glass's most outstanding properties is its great stability or chemical inertness. The resistance which glass offers to the attack of water, to weathering which is due primarily to water and carbon dioxide, and to the attack of aqueous solutions of acids (except hydrofluoric), bases, and salts is the main reason why glass is used so widely for the storage of foods, drugs, and chemicals, for chemical laboratory apparatus, and for chemical plant equipment such as containers, pipeline, and pump parts. The *chemical durability* of glass is the lasting quality (both visible and chemical) of its surface. It is frequently evaluated, after prolonged weathering or storing, in terms of chemical and physical changes in the glass surface, or in terms of changes in the contents of a vessel.

No accelerated laboratory test or practical series of tests has been devised to give a general numerical value for chemical durability, and results of the various tests must be used in combination with a background knowledge of actual service experience.

Certain commercial borosilicate glasses have good all-round corrosion resistance; 96% silica glass has very superior chemical durability and in this respect, as well as in others, compares very favorably with fused quartz. The 96% silica glasses, moreover, have an advantage over fused quartz in that they can be fabricated more feasibly into larger and more intricate articles.

9. FABRICATION OF INDUSTRIAL GLASSWARE

Cold glass cannot be turned in a lathe, surfaced in a shaper, or drilled with a machine drill. In other words, it cannot be worked with a cutting tool bit. The drilling of small holes, 1/4 in. in diameter or less, by a triangular piece of hard steel or Carboloy, fed with turpentine and operated in a drill press, might seem to be an exception. Larger holes can be made with a metal cylinder having a serrated end, operated in a drill press, and fed with a mixture of water and abrasive particles.

On the other hand, glass can be ground very much as metals except for slower speeds and extra mounting precautions. It can be polished to a much smoother surface. Relatively large cylinders can be cut by a variety of simple "crack-off" methods. With small sizes of rod and tubing, a scratch with a diamond or carbide wheel glass cutter allows the glass to be broken off squarely by putting the scratched region into tension. A more effective way of cutting thicker-walled tubing is to place an electrically heated Nichrome wire in a file scratch around the tubing and then put cold water on the scratched region. Heavy pieces can be sawed with abrasive or diamond wheels.

Crews can be quickly trained to do fitting of glass piping in the field with the hot-wire crack-off and high-frequency electric sealing methods.

Yellow hot glass is quite moldable and can be blown or pressed into complex shapes. A variety of mass-production methods exists for shaping hot glass as it emerges from the melting tank. Also, cold glass can be reheated and then reshaped and welded.

Glass is being applied in a great and growing diversity of ways in industry. Glassware, produced for industrial purposes in great volume, is made by a variety of mass-production methods of automatic fabrication.

Three principal methods—blowing, pressing, and drawing—are used for forming the ware from glass in the hot, moldable state. Each method is suitable for certain types and shapes of ware, and each method, as well as the nature of glass, imposes some restrictions on design and weight.

Sheet glass is made by drawing molten glass continuously and directly from continuous-melting tank furnaces and passing it right on through annealing ovens. Plate glass has more or less the same soda-lime composition as sheet glass and is fabricated by two processes. In the intermittent method, molten glass is poured from pots in front of iron forming rolls and flattened. After annealing, the sheets are ground to a greater flatness and polished. In the continuous process, a stream of molten glass flows from the tank to water-cooled rollers which shape an endless flat ribbon of uniform width and thickness. After annealing, or lehring, the ribbon is cut, inspected, and passed through continuous grinding and polishing machines.

Flat forms of special compositions, such as for heat-resistant windows, color filters, or electrical insulators, are generally made by pressing molten glass in iron molds. For the accurate control of the light from modern high-intensity sources, Fresnel prisms are pressed with precision in the surfaces of glass panels.

Cylindrical tubing and rods are drawn automatically and continuously from the molten glass in the tank. The tubing ranges in diameter from about $^1/_8$-in. up to 4 $^1/_2$-in. OD, with various wall thickness ranging up to $^1/_4$ in. for the large OD sizes. The maximum length of pieces of flanged piping is 20 ft. The rods range up to 2 in. in diameter and 15 ft in length.

Blown glassware is made by inserting an elongated, thick-walled bubble of yellow hot glass, which is attached to a hollow blowing iron part, into an iron mold and blowing the glass out against the mold. This gives an article which is correct in shape and size in one operation except for cutting off the excess part which is attached to the blowing mechanism. With cylindrical ware that permits rotation in the mold during blowing, the iron mold is lined with a wet carbonaceous paste that generates a steam cushion for the glass to ride on. This results in an article with a surface that is glossier and smoother than that obtained with pressed ware or with ware blown in a "hot iron" mold where there is no lining and, of course, no rotation. A "hot iron" mold has to be used whenever the blown ware is nonsymmetrical about an axis or has raised lettering or other projections.

The automatic manufacturing of bottles is an example of "press-blow" fabrication which results in an article requiring no subsequent shaping operation. A blank of hot glass is pressed by forming dies which shape the neck complete with a screw thread and which also partially form the cavity part of the bottle. Then, while the glass is still hot enough for further shaping, it is inserted automatically into a blow mold, and the shaping is completed by blowing.

For pressed ware, a lump of hot glass of a definite weight is fed into an iron mold, and an iron plunger is moved down to close the opening in the retainer ring. Then with relatively low pressure the plunger is forced down until the glass fills the cavity formed between the plunger and the mold and hardens. A few degrees of taper must be allowed on the plunger so that it can be withdrawn. Hinged molds often are used for more complicated shapes; and for special articles the plunger extrudes the glass into a multiplicity of mold cavities in a "font" mold.

Some articles are made by fusion-sealing together two or more parts that have been made by the above processes, for example, lightning arrestor bodies for power-line use and large television tube envelopes. Flanged pipe has pressed flanges sealed to drawn tubing.

Multiform glass products are made by cold pressing or cold casting powdered glass, followed by a firing to give perfectly vitreous articles that may have holes, grooves, and screw threads and that may be accurate to a few thousandths of an inch in some dimensions without requiring any finish shaping.

After shaping, glassware is usually annealed and then may be treated by one or more of the following finishing or related operations: inspection, tempering, removal of excess glass, grinding and polishing, cleaning in special cases, precision finishing, calibration, attachment of metal parts, metalization for solder sealing to metal parts, making of holes, reworking and welding by flame heating or high frequency electric heating, and frosting.

PRINCIPAL INDUSTRIAL APPLICATIONS. **Chemical** (for food- and drug-processing industries and for chemical industries; for the most part of low expansion chemical- and heat-resistant glasses): containers, tanks, jars, piping, centrifugal pump parts, laboratory ware, tubing for heat exchangers, cylinders for fractionating columns, sight and gage glasses, and Godet wheels for pulling rayon thread out of acid baths.

Electrical and Electronic: insulators, lightning arrestor bodies for power-line use, ribbon glass condensers, fuse plug bodies, x-ray tube envelopes and x-ray absorbing sheet or molded shields, electronic tube envelopes and tubing, mercury switches, metalized glass for hermetically sealed containers, metalized glass electronic components, and special glasses for matched expansion glass-metal fusion seals.

Lighting: incandescent lamp envelopes, fluorescent lamp tubing, sign light tubing, projection lamp envelopes and cover lenses, diffusing glassware, and lens-action prismatic light-controlling glassware.

Light Filters and Colored Signalware: ultraviolet transmitting: germicidal lamp tubing, sun-lamp bulbs, blacklight vision tubing and bulbs; heat or infrared transmitting: heat-lamp bulbs, blacklight vision filters; and colored glass for filters and for signalware that often has accurate prismatic surfaces on cylindrical, flat, or lens shapes.

Thermal: heat exchanger tubing, furnace windows, induction furnace crucibles, calcining jars or trays, thermocouple protection tubes, heat-absorbing sheet glass, furnace cores or linings, Thermos and Dewar flasks, thermometer tubing, heat-insulation Foamglas, heat-insulation Fiberglas products, and heat-insulation double-glazed (air-space) windows.

Optical: instrument lenses, prisms, mirrors, eyeglasses, and goggles.

Mechanical: jewel bearings for precision instruments, optically flat surface plates, machinists' gages, torsion fibers, paraboloidal reflector shells for sealed-beam headlamps (made by pressing), accurate bore tubing for gas and liquid flowmeters, blueprint cylinders and sheets, molds for rubber and plastics, vacuum pumps (diffusion types), lubricator and oil cups, rollers for yarns and thread, Fiberglas filters, slide valve disks for gas-meter valves, rotary valve seats, Fiberglas textiles, humidifier floats, multiform glass pipeline filters, centrifuge containers, and level vials.

Acoustical: Fiberglas wool for sound absorption.

Structural: laminated safety-glass windshields; tempered sheet for doors, machine windows, fire screens, and pickling tanks; building blocks; Fiberglas-plastic board of very high strength-to-weight ratio; cases and covers; ultra-low expansion spacers; mirror disks for ultra-precision reflecting telescopes; and Foamglas floats.

PLASTICS

By John J. Martin

Prior to the development of modern synthetic resins, the most important components of plastics were natural resins such as copal, rosin, pitch, amber, and shellac. Depending on the purpose, these resins were mixed with various types of fillers. In general, these materials were limited in strength and resistance to heat; consequently their use as structural materials was severely restricted. Most of these resins are now used in large quantities in varnishes. Shellac also is still employed as a molding composition for phonograph records and in laminated electrical insulations.

The modern plastics industry in this country originated with the work on Celluloid (cellulose nitrate) in 1869 and received its greatest stimulus in 1909 with the introduction of the first commercial synthetic resin, Bakelite, which was produced by certain reactions between phenol and formaldehyde. A chemical classification of plastics and synthetic elastomers published by the government during 1943 lists approximately 100 items.

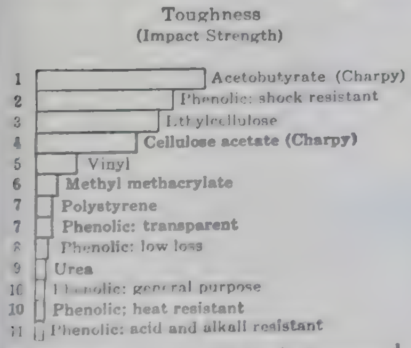

Fig. 1. Toughness of plastics compared. (Reprinted from Bakelite Corporation's *Comparator*)

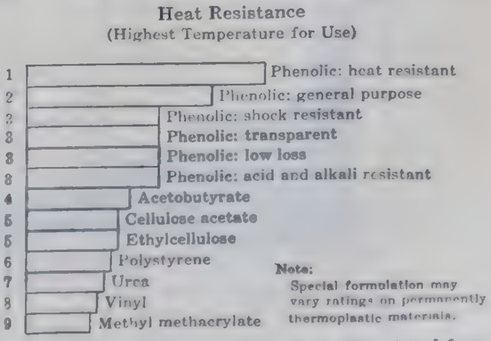

Fig. 2. Heat resistance of plastics. (Reprinted from Bakelite Corporation's *Comparator*)

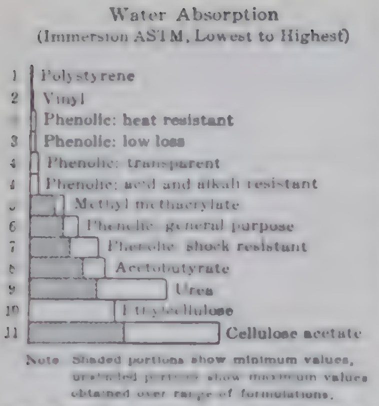

FIG. 3. Water absorption of plastics. (Reprinted from Bakelite Corporation's *Comparator*)

These materials are as unlike among themselves as the different metals which the design engineer knows have varying properties, depending on the additive element used to form the desired alloy. For example, specifications for one of the commonly used plastics (cellulose acetate) include four types and thirteen grades. Even with all these variations to meet the specifications, special materials have to be compounded for particular applications. For this reason, engineers should consult the manufacturers before making a choice of material in order that they may avoid wrong applications which not only result in financial loss but also give an entirely erroneous impression of the usefulness of plastics. A list of material manufacturers is contained in the *Encyclopedia of Plastics* published by Plastics Catalogue Corporation, 122 East 42 Street, New York, N. Y.

The noun "plastic" has been defined by the American Society for Testing Materials as follows:

"A plastic is a material which contains as an essential ingredient an organic substance of large molecular weight, is solid in its finished state, and, at some stage in its manufacture or in its processing into finished articles, can be shaped by flow."

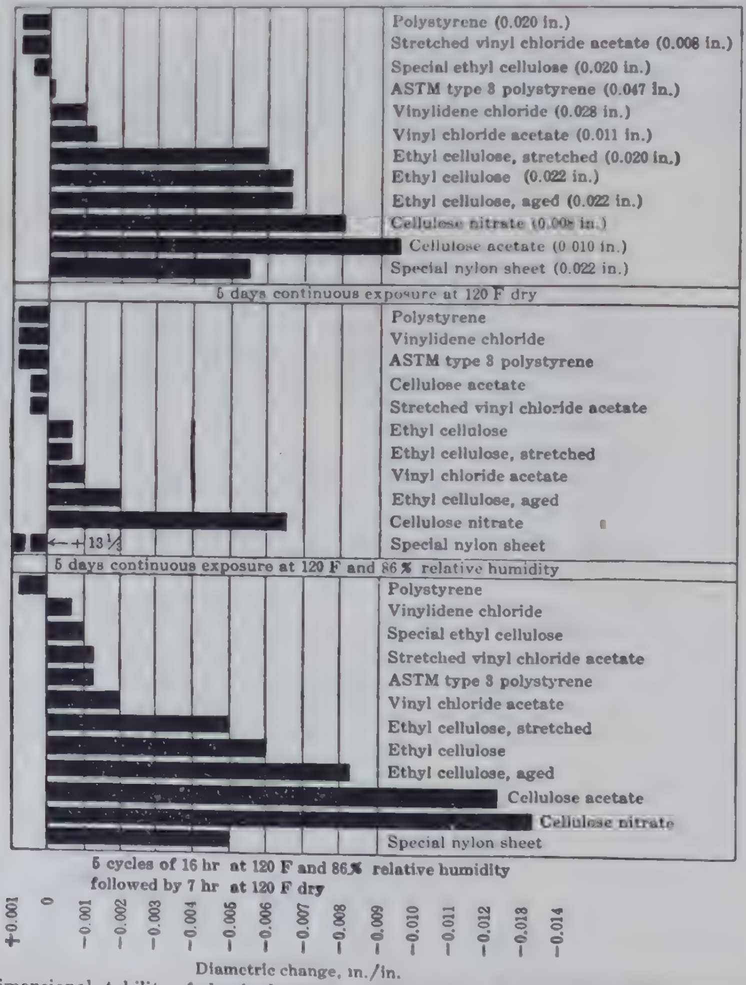

FIG. 4. Dimensional stability of plastic sheeting. (Reprinted by permission from Dimensional Stability of Plastics, by Robert Burns, *ASTM Bulletin*, May, 1945)

THERMOPLASTIC MATERIALS. "The adjective *thermoplastic* means capable of being repeatedly softened by increase of temperature and hardened by lowering of temperature. *Thermoplastic* applies to those materials whose change upon heating is substantially physical." (ASTM definition.)

THERMOSETTING MATERIALS. "The adjective *thermosetting* carries the meaning as stated of changing into a substantially infusible or insoluble product when cured under application of heat or chemical means." (ASTM designation.)

PLASTICIZERS. Most thermoplastic resins, particularly the cellulose derivatives, are not fusible enough to be molded or softened without thermal decomposition. In such cases, it is necessary to add a softening agent or plasticizer to develop such properties as resiliency, elasticity, and flexibility. These plasticizers are not capable of forming resinous products in themselves and should not be confused with plastics. They are liquid, semiliquid, or solid. Examples are dibutyl phthalate, diethyl phthalate, tricresyl phosphate, diethoxy ethyl phthalate, and dibutyl sebacate. The nature and amount of plasticizer

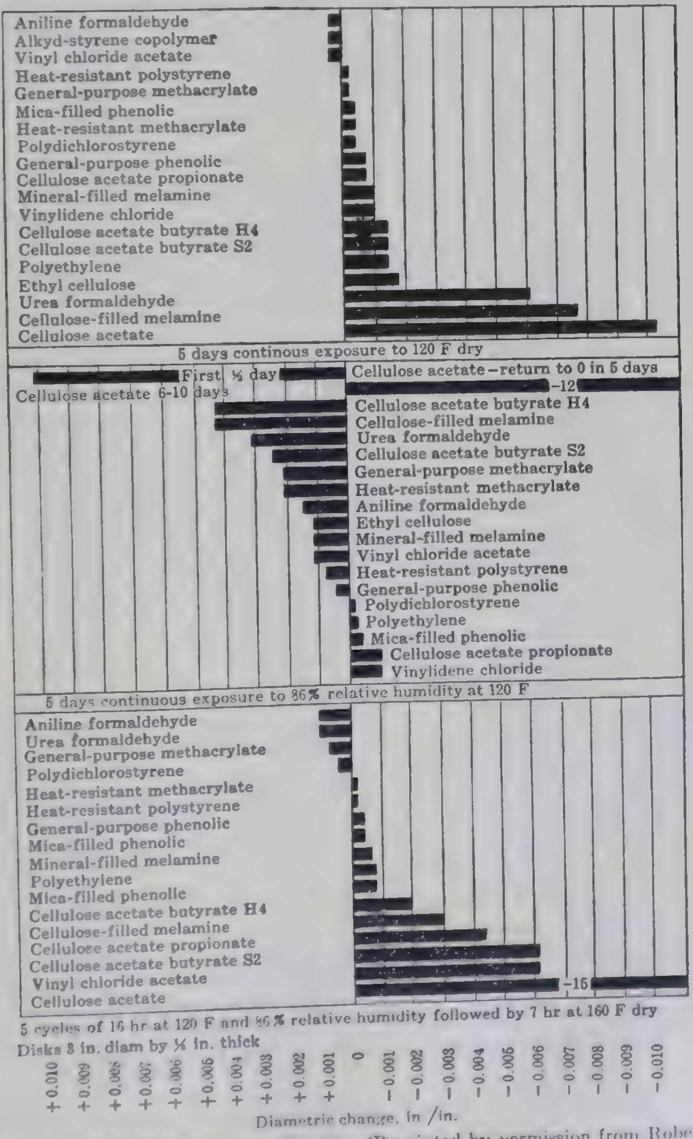

FIG. 5. Dimensional stability of molded plastics. (Reprinted by permission from Robert Burns, *loc. cit.*)

has an important bearing on the physical properties of the resulting plastic. A gain in one property generally is obtained at a sacrifice of another which accounts for the wide spread in the physical properties given in the various tables of this section.

COMPARATIVE PROPERTIES. As a general guide to the properties of various types of plastics, their toughness, heat resistance, and water-absorption characteristics are compared in Figs. 1, 2, and 3. Dimensional stability of sheeting and of molded plastics are compared in Figs. 4 and 5.

10. THERMOPLASTICS

CELLULOSE NITRATE. Cellulose nitrate compounds, commercially known as Celluloid, Pyralin, Nitron, and Nixon CN, are plastics formed by treating cotton or purified wood cellulose with sulfuric and nitric acids. After nitration, the spent acid is removed, and the cellulose nitrate is thoroughly washed and "wet" with alcohol, as it is not safe to store or ship it when dry. Camphor, a commonly used plasticizer, is mixed with the alcohol-wet cellulose nitrate mixture which is then strained. The remaining mass of plasticized cellulose nitrate is kneaded on heated rolls while the desired colors are added and the alcohol is allowed to evaporate. It is then ground into proper grain size for molding. If the material is to be made into sheets, slabs from the rolls are pressed into cakes and then cut into sheets. Tubes or rods, or continuous sheet, can be formed by extruding the mass from the rollers. For these, the material must be allowed to age to remove the remaining solvent.

Cellulose nitrate has good chemical resistance to solvents other than alcohols, ketones, and esters. Because this plastic is highly inflammable and tends to become yellow and brittle with age, the material has limited applications. Cellulose nitrate is used for handles for small tools, mallet heads, spectacle frames, dials and crystals for clocks and instruments, drawing instruments, toys, etc. Its properties are listed in Table 1.

Table 1. General Range of Properties of the Cellulose Compounds

Material	Specific Gravity	Cost, dollars/lb	Water Absorption in 24 hr, %	Tensile Strength, psi	Flexural Strength, psi	Impact Strength (Izod) at 77 F, ft-lb/in. of notch	Linear Thermal Expansion, in./in./°C
Cellulose nitrate	1.35-1.57	0.50-1	1.0-4.0	3000-8000	4000-12000	1.0-6.0	$9\text{-}16 \times 10^{-5}$
Cellulose acetate	1.27-1.34	0.35-0.54	2.0-5.0	1500-8000	3000-12000	0.5-6.0	$8\text{-}16 \times 10^{-5}$
Cellulose acetate butyrate	1.18-1.25	0.47-0.61	1.7-2.4	1400-7000	2000-12000	0.6-9.0	$11\text{-}17 \times 10^{-5}$
Cellulose propionate	1.17-1.22	0.61-0.68	1.0-1.7	2000-6500	3000-10500	0.5-11.0	$13\text{-}16 \times 10^{-5}$
Ethyl cellulose	1.09-1.16	0.58-0.65	0.8-1.8	2000-8000	4000-12000	2.0-8.0	$10\text{-}20 \times 10^{-5}$
ASTM Test Method	D792		D570	D638	D790	D256	D696

Note: ASTM procurement specifications for cellulosic molding compounds: cellulose nitrate, D701; cellulose acetate, D706; cellulose acetate butyrate, D707; ethyl cellulose, D787.

CELLULOSE ACETATE. Cellulose acetate compounds commercially known as Tenite I, Lumarith, Plastacele, Bakelite Cellulose Acetate, Fibestos, and Chemaco CA, etc., are plastics made from cotton linters which are dissolved in a mixture of acetic acid and acetic anhydride, with sulfuric acid or other catalyst. A calculated amount of water, sufficient to cause hydrolysis but not precipitation, is added to the heavy syrup resulting from this treatment, and the syrup is allowed to "ripen" or stand until the original triacetate has hydrolyzed to an acetate of the desired acetyl content. After this action is completed, the cellulose acetate solution is plunged into cold water which precipitates the cellulose acetate into small flakes. These flakes are thoroughly washed and dried. In the manufacture of cellulose acetate molding compounds, plasticizers and related compounds are added either by means of solvents or hot-mix methods to bring the cellulose into a homogeneous mass. The choice and blending of the plasticizers influence the properties of this material. The material is then cooled and ground into molding powder.

For making sheet or film, the dried plastic is mixed with a plasticizer, color is added if required, and the mass is worked on a hot roll. The slabs from the roll are pressed into cakes, cut into sheets, and seasoned. Rods and tubes can be extruded to the desired size and shape. Sheet material especially 30 mils or over in thickness is also produced by extruding. The films are cast on a drum.

Cellulose acetate compounds are similar to cellulose nitrate compounds but show considerable improvement in many respects. They are slow burning and are easily molded by conventional methods. Strong acids, alkalies, and acetone dissolve the cellulose acetate compounds. Their chief disadvantage is their comparatively poor dimensional stability under adverse atmospheric conditions.

Typical commercial applications of these compounds are name plates, flashlight cases and lenses, tool handles, terminal blocks, interleaving in relay coils and other wound coils, backing for electrical grades of pressure sensitive tapes, etc. The properties of cellulose acetate are listed in Table 1.

CELLULOSE ACETATE BUTYRATE. Cellulose acetate butyrate compounds, commercially known as Tenite II, etc., are similar in preparation to cellulose acetate compounds except that butyric acid is used in addition to the acetic acid and acetic anhydride. This facilitates the production of molding materials that have better moisture resistance and improved dimensional stability. A disadvantage of the cellulose acetate butyrates is that they may have an unpleasant odor. Molded materials have been used for producing such items as gun stocks, auto steering wheels, combined telephone-set housings, building hardware, etc. For properties of this material, see Table 1.

CELLULOSE PROPIONATE. Cellulose propionate compound is produced through the reaction of propionic acid and propionic anhydride with cellulose in the presence of a catalyst, the flake being mixed in the usual manner with plasticizers, color, etc. It is an unusually stable cellulosic compound comparing favorably with cellulose acetate butyrate. The material is sold under the trade name of Forticel. Its properties are listed in Table 1.

ETHYL CELLULOSE. Ethyl cellulose is produced by the action of a strong alkali such as sodium hydroxide upon cellulose and by treatment of the resulting product with ethyl chloride or ethyl sulfate. In common with the other cellulosics, it is compounded with plasticizers, colors, etc. The chief improvement of this material over other cellulosics is its low-temperature flexibility, high-temperature stability, and high dielectric properties. It has the disadvantage, however, of softening with carbon tetrachloride and alcohol, both of which are common in many cleaning processes. The material is known commercially as Ethocel, Lumarith E.C., Chemaco E.C., and Nixon Ethyl Cellulose. It is used for containers, flashlight cases, etc.

POLYVINYL CHLORIDE. Monomeric vinyl chloride, with a boiling point of −13 C, is a gas at room temperature. Under suitable conditions of heat and pressure and in the presence of catalysts, vinyl chloride is transformed to a white fluffy polymer. The polymer, when plasticized, can be molded under heat and pressure to give nonrigid materials characterized by low moisture absorption and inertness to a variety of chemical solvents, as well as by resistance to flame. Since plasticized polyvinyl chloride is too soft to serve as a rigid molding material, it is generally copolymerized with vinyl acetate. This process will be discussed later.

The polyvinyl chloride resins known as Koroseal, Geon, etc., are used for producing films, sheets, tubing, wire and cable coatings, belts, watch straps, chemical and water-resistant fabric coatings, etc. Their properties are shown in Table 2.

Table 2. Approximate Physical Properties of Polyvinyl Chloride and Vinyl Chloride Acetate Compounds

Properties	Rigid Vinyl Chloride Acetate Resins	Nonrigid Polyvinyl Chloride Resins
Specific gravity	1.35–1.45	1.18–1.65
Tensile strength, psi	4,500– 8,000	1000–3000
Impact strength (Izod), at 77 F, ft-lb/in. of notch	0.25–0.75	....
Flexural strength, psi	7,500–14,500	....
Linear thermal expansion, in./in./°C, below 55–65 C	6.9×10^{-5}	....
Water absorption in 24 hr, %	0.05–0.15	0.10–2.25
Cost, dollars/lb	0.59–0.81	....

POLYVINYL ACETATE. Vinyl acetate is a volatile liquid which boils at 73 C. The vinyl acetate monomer is obtained by reaction of acetylene with acetic acid in the presence of suitable catalysts. The monomeric acetate can be polymerized to form resins. Polyvinyl acetate resins occupy a unique position in the vinyl resin field in that they are also used as starting materials for the production of other resins. However, the acetate is not used by itself for molded application because of its low softening temperature and high cold flow.

The polyvinyl acetate resins are soluble in a wide range of organic liquids. They have exceptionally good resistance to greases and oils and are used for coating grease-proof paper and containers.

POLYVINYL CHLORIDE ACETATE. Vinyl chloride acetate molding compounds, commercially known as Vinylite, Tygon, etc., are copolymers of vinyl acetate and vinyl chloride formed by the reaction of these materials in the presence of a solvent and a catalyst. The proportional amounts of the two esters can be varied over a wide range for specific purposes. The most useful vinyl chloride acetate copolymers contain 85% or more of vinyl chloride.

These molding compounds exhibit high resistance to humidity and chemicals and are difficult to ignite. However, they have a low temperature limit precluding their use for applications where the molded parts may operate at elevated temperatures. The compounds are used commercially for phonograph records, watch crystals, safety goggle frames, straps, belts, etc. The properties are given in Table 2.

POLYVINYL ALCOHOL. Polyvinyl alcohol is prepared by hydrolysis of polyvinyl acetate. The conditions under which hydrolysis takes place have an important bearing on the properties of the finished material. When completely hydrolyzed the alcohol is soluble in hot water, and when suitably compounded it is used to coat or impregnate textiles, paper, etc.

The compounds are highly resistant to hydrocarbons and to most organic solvents of the ester, ether, alcohol, and chlorinated hydrocarbon classes, as well as carbon disulfide. They are completely unaffected by oils, fats, or greases. Films prepared from polyvinyl alcohol are tough and highly impermeable to most gases.

Polyvinyl alcohol compounds can be extruded as seamless, flexible tubing, either plain or reinforced with braided fabric or wire. Because of the water solubility of polyvinyl alcohol, these products cannot be employed for handling water or aqueous solutions. Such materials are sold in the trade under the names of PVA and Resistoflex.

POLYVINYL BUTYRAL. Polyvinyl butyral resins were developed specifically for safety-glass sheeting. This plastic, commonly known as Butacite, etc., is outstanding for its toughness, adhesive characteristics, clarity, and resistance to shock, even at low temperatures. The resin may be manufactured by the reaction of butyraldehyde with polyvinyl alcohol.

Safety-glass sheeting is made either by calendering, or by extruding as a thick solution and evaporating the solvent. To make the laminated safety glass, the plastic sheeting is inserted between two clean glass plates which are bonded together by means of heat and pressure. It is also used between sheets of methyl methacrylate to protect enclosures of pressurized cabins of airplanes against shattering.

POLYVINYLIDENE CHLORIDE. The basic raw materials of the vinylidene chloride resins are petroleum and brine. Ethylene from petroleum and chlorine from brine combine to form monomeric vinylidene chloride, a clear colorless liquid with a boiling point at about 89 F.

Vinylidene chloride is polymerized by a number of catalysts such as peroxides. The most useful polymers are not produced from vinylidene chloride alone. They are chiefly copolymers of vinylidene chloride with other unsaturated compounds. Vinyl chloride is generally used. The copolymers of vinyl chloride and vinylidene chloride are sold in the trade under the name of Saran. The material is quite resistant to water, acids, alkalies, and organic solvents.

Vinylidene chloride is utilized in the fabrication of gaskets and valve seats. Tubing is used for handling certain fluids in refrigeration and air-conditioning equipment. Molded couplings of polyvinylidene chloride are available for both tubing and pipe. Cold-stretched monofilament, in diameters of 0.007 to 0.100 in., is employed in woven textiles for automobile and airplane upholstery, fishing leaders, and corrosion-resistant, partially transparent screening. It is claimed that the screening will outlast any metal screening; it is not affected by fungus and will not burn. Vinylidene chloride is also available in film form for packaging.

METHACRYLATE. Methacrylate molding compounds, commercially known as Lucite and Plexiglas, are produced by treating an acetone compound with methanol in the presence of sulfuric acid, and polymerizing the resulting methyl methacrylate. Heat, light, and oxygen serve as polymerizing accelerators.

These materials are particularly valuable for their crystal clarity and for their outstanding optical properties. Molded parts made from methyl methacrylate resin are brittle compared to the cellulosic plastics, but they have reasonably good scratch-resisting properties. They do not shatter like glass when broken.

Methacrylate resin is also used in large quantities in the form of cast sheets, rods, and tubes. The sheets are available in thicknesses from 0.060 to 2.50 in. Rods are furnished up to 2 in. in diameter. The tubes are manufactured in various wall thicknesses and diameters.

The properties of cast products are similar to those of molded resins. They are resistant to moisture or aqueous solutions of mineral salts and alkalies. Solvents include acetone, toluene, chloroform, and ethylene dichloride. These products are attacked by a number of alcohols, esters, ketones, aromatic hydrocarbons and chlorinated solvents.

If subjected to excessive fiber stress, methacrylates will craze, i.e. develop tiny cracks, and thereby destroy their desirable optical properties.

Molded and cast materials are used for aircraft and marine windows, lenses, dials, handles, dentures, watch crystals, radiator ornaments, draft gages, edge-lighted instrument panels, transparent models, traffic directors, miscellaneous novelties, and costume jewelry. Properties are given in Table 3.

Table 3. Approximate Physical and Electrical Characteristics of Acrylic, Polystyrene, and Polyethylene Resins

Property	Methacrylate Molding Compounds	Polystyrene Molding Compounds	Polyethylene Molding Compounds
Specific gravity	1.2	1.05–1.07	0.92
Tensile strength, 1000 psi	6–10	5.5–9.0	1.7–3.0
Flexural strength, 1000 psi	12–17	8.0–19.0	1.6
Impact strength, (Izod) at 77 F, ft-lb/in. notch	0.2–0.5	0.25–0.40	>4
Thermal expansion in./in./°C	9×10^{-5}	$6\text{–}8 \times 10^{-5}$	$16\text{–}18 \times 10^{-5}$
Water absorption in 24 hr, %	0.5	0.05	<0.01
Dielectric constant, 10^6 cycles	2.7–3.2	2.6	2.3
Power factor, 10^6 cycles	0.02–0.03	0.0001–0.0005	0.0003
Refractive index, n_D	1.5	1.6	....
Cost, dollars/lb	0.65–0.80	0.27–0.42	0.49–0.56
ASTM procurement specification	D788	D703	....

POLYSTYRENE. Polystyrene molding compounds, commercially known as Styron, Lustron, Loaline, Bakelite Polystyrene, etc., are made by forcing ethylene, made from natural gas or petroleum, through benzene, a by-product from coke ovens, in the presence of a suitable catalyst, such as ethyl chloride, to produce ethyl benzene. This material is then decomposed under heat, hydrogen splitting away from the rest of the molecule to form the monomeric styrene. Polystyrene is prepared by polymerization.

Polystyrene molding compounds have excellent electrical properties, especially at the higher frequencies. Resistance to alkalies is excellent, but some strong acids attack the resin. Polystyrene has low specific gravity, excellent dimensional stability, and remarkably low moisture absorption. Although it has reasonably good tensile strength, it is somewhat brittle. It is another of the few plastics suitable for making optical lenses. Perhaps the greatest disadvantage of polystyrene compounds is their tendency to craze and crack. This can be alleviated to some extent by heat treating. Polystyrene is also furnished in film form and is used in the construction of condensers and coils.

A great amount of effort has been expended toward developing high-temperature-resistant polystyrenes. Polystyrene P-8 produced by the Chemical Division of the Koppers Company and Cerex X-250 manufactured by the Monsanto Chemical Company are examples of such materials.

Polystyrene is unique among plastics in that it gives a somewhat metallic ring when dropped on a hard surface or struck sharply. This property can often be used as a simple test to distinguish it from other plastics.

Polystyrene molding compounds find their greatest application in electrical insulators. In certain optical applications they are used similarly to methacrylate molding compounds. Polystyrene is also being used for making a number of parts for the refrigerator industries.

Applications of polystyrene involving chemical resistance include articles such as closures for chemical bottles, photographic equipment, battery cases, etc. The properties of typical materials are given in Table 3.

STYRENE COPOLYMERS. Styrene was one of the materials used in the wartime synthetic rubber program and for this reason was in good supply after the war.

Little information is available pertaining to the formulation or preparative methods of many styrene materials. When copolymerized with other materials, styrene yields heat-resistant copolymers. Included among these materials are Textolite 1421 and 1422 cast plastics which are available in sheets and rods. These materials cost $1.40 to $10.50 per lb, depending on their shape. Electrical properties of Textolite 1421 and 1422 are comparable to those of polystyrene, but the materials have a much higher heat distortion point. The materials can be machined to close tolerances, and they retain their shape and strength at elevated temperatures. Textolite 1422 is dimensionally stable in the temperature range of 250 to 300 F. It is not moldable, but castings can be fabricated into structural shapes for equipment requiring a low-loss material and operating at a temperature unsafe for polystyrene.

A styrene copolymer known as Plexene M has been developed to combine high heat resistance, greater strength, improved machining qualities, and better weathering characteristics with many of the excellent properties of the styrene polymers. Moldings made of Plexene M do not show the marked tendency to crazing, characteristic of many unmodified styrene compounds. Although the dielectric properties are not so desirable as those of polystyrene, physical strength characteristics are exceptionally high in relation to the low specific gravity (1.08) of the material. The material is resistant to acids, alkalies, dilute alcohol, and gasoline. Plexene M is available at about 65 cents per pound.

Another group of styrene copolymers which possess qualities of both rubberlike materials and rigid thermoplastics are sold under the trademark Styraloy. These resins, having a specific gravity of 0.95 to 0.97, vary from flexible materials in thin sections to fairly rigid products in thick sections. Styraloy 22 was developed during the war primarily for a one-piece cable sheathing with a low power loss at high frequencies, a low temperature flexibility, and minimum cold flow at elevated temperatures. Styraloys, like natural rubber, are attacked by common solvents, but to a lesser degree. They have good resistance to strong mineral acids and strong alkalies. They are now finding many applications in the aviation, automotive, and chemical industries.

UNSATURATED POLYESTER CAST PLASTICS. The industrial applications of these materials, sometimes referred to under the generic term cross-linked addition polymers, are rapidly expanding. The polyesters consist essentially of plastics in liquid form, with or without fillers, which are poured into suitable molds and polymerized by the use of a catalytic agent and the application of heat. Room temperature cures are frequently feasible. The resultant plastic is hard, dense, and thermosetting in nature. Most commercial materials are mixtures of styrene and polyester monomers, the mixture undergoing a volume shrinkage of about 12% when cured. Although the relatively large degree of shrinkage frequently causes cracking around inserts, this difficulty is sharply reduced by the judicious use of fillers. These polymers are in general satisfactorily resistant to organic solvents, acids, alkalies, and oxidizing agents.

A reduced degree of cross-linking is possible in this class of polymers, producing a rubbery-type mass. Such materials are promising for potting and filling operations where resistance to shock as well as to moisture is essential.

Cross-linked addition polymers are commercially available as Laminac, Selectron, Vibrin, Paraplex, MR-Resins, etc.

Properties of the rigid castings are shown in Table 4.

Table 4. Approximate Properties of Polyester Cast Plastics

Specific gravity	1.20
Tensile strength, psi	6,000
Flexural strength, psi	15,000
Modulus of elasticity, flexure	$3–8 \times 10^5$
Impact at 77 F, Izod ft-lb/in. notch	0.3–0.4
Hardness	M90
Water absorption in 24 hr, %	0.50
Power factor, 10^6 cycles	0.03
Dielectric constant, 10^6 cycles	3.5
Dielectric strength, v/mil (short time)	450

ALLYL CASTING RESINS are available from the manufacturer in the form of liquid monomers. Transparent cast sheets are also furnished by the suppliers. The allyl monomers, like the polyesters, can be cast polymerized by the fabricator in simple molds. Iron and steel, aluminum, low-melting alloys, glass, and glazed ceramic molds may be used to form thermosetting parts. The allyl resin can be cured at moderate temperature and need not be pressurized during the cure.

Castings made of allyl resin are resistant to chemicals and solvents. They also have good resistance to abrasion and marring. The mechanical properties of these materials are quite similar to those of the polyesters.

They may be employed for such parts as dial, indicator, and gage covers; aircraft enclosures; heat-resistant electric insulating components; decorative novelties; television lenses, etc.

Allyl casting resins, in the liquid monomer form, are commercially available as Laminac, Kriston, and Allyl Diglycol Carbonate.

POLYETHYLENE. Polyethylene molding compounds, known commercially as Polythene and Bakelite Polyethylene, are made by the high-temperature, high-pressure polymerization of ethylene. A commonly used catalyst is oxygen in very small quantities.

The compounds are resistant to both alkalies and acids and to most of the organic solvents. They are extremely flexible and tough over a wide range of temperatures. Like polystyrene, they have excellent electrical properties and a low specific gravity. Their resistance to water and vapor is exceptionally good. The materials are used for wire and cable insulation, acid-resistant clothing in the chemical industry, shower curtains, etc. Their properties are shown in Table 3.

SYNTHETIC POLYMERIC AMIDES. Nylon is a generic term that was assigned by E. I. du Pont de Nemours and Co to a whole group of long-chain synthetic polymeric amides which have recurring amide groups as an integral part of the main polymer chain and are capable of being formed into a filament in which the structural elements are oriented in the direction of the axis.

Although the greatest volume of the material is used as yarn for making stockings and other textile items, molded articles from nylon powders are steadily increasing in use. These include coil forms, slide fasteners, bearings, tableware, etc. The molding powders are quite costly, the price ranging from $1.60 to $4.50 per lb. Nylon is also available in sheet, tube, and rod form.

The physical and electrical properties of several nylon molding compounds are given in Table 5.

Table 5. Properties of a Few of the Nylon Molding Compounds

(The material included in this table appeared in E. I. du Pont de Nemours & Company, Catalog issued by their Plastics Department, 1948. Reprinted by permission.)

Properties	ASTM Test Method	FM-10001	FM-3001
Specific gravity	D-792	1.14	1.09
Tensile strength, 77 F, psi	D-638	10,900	7,000
Elongation, 77 F	D-638	50	135
Modulus of elasticity, 77 F, psi	D-638	400,000	260,000
Flexural strength, 77 F, psi	D-790	14,600	9,500

Dielectric constant, 10^6 cycles	D-150	3.4	3.5
Power factor, 10^6 cycles	D-150	0.04	0.03
Water absorption, %	D-570	1.5	0.4

POLYTETRAFLUORETHYLENE. This plastic, known as Teflon, is most oustanding from standpoints of high temperature and chemical resistance. It is produced by polymerizing gaseous tetrafluorethylene to yield a solid granular polymer. It is claimed that the material does not soften appreciably until temperatures of about 500 F have been reached and will resist attack by all acids including boiling aqua regia. It is also claimed that no substance has been found that is capable of dissolving or swelling polytetrafluorethylene. It is suggested for use as a gasket and packing material, as tubing for chemical process work, and for electrical applications where low dielectric losses and high heat resistance are essential. (See Table 6.) It can be extruded in the form of rods and tubes or as wire coating, and compression moldings of simple articles can be made by special techniques.

TRIFLUOROCHLOROETHYLENE (Kel-F), like Teflon, is another high-temperature compound. The material is produced by M. W. Kellogg Company, of Jersey City, New Jersey. Made up of fluorine and chlorine to the extent of four-fifths of its weight, it is related to the new family of organic compounds, the fluorocarbons, which reached practical development during the war. It is understood that this material is extremely resistant to concentrated sulfuric, hydrofluoric, and hydrochloric acids. The material is reported to be suitable for use at temperatures as high as 400 F and also at very low temperatures. It absorbs no water and has a very low water-vapor transmission.

The electrical properties of Kel-F are excellent, and the material should provide good electrical insulation for parts exposed to extremes of temperature and to corrosive or humid atmospheres.

CASEIN (Protein). The raw material for casein plastics is skimmed milk, which is treated with rennet under controlled conditions to give a curd consisting of a loose complex of the calcium phosphate of the protein components of the milk. After being washed and dried, the curd is obtained as a coarse powder, known as rennet casein. In the manufacture of plastics material, the rennet casein is ground to a fine powder and mechanically mixed with about 30 to 40% of its weight of water until the water is absorbed to give individual particles of casein gel which is extruded in rod form from screw-type extruders.

Table 6. Typical Properties of Teflon

(Data from du Pont's *Technical Service Bulletin* 13, April 1, 1949. Reprinted by permission.)

Data given represent standard commercial grades of material and standard methods of testing except where otherwise noted.

Property	Value		Method
Specific gravity	2.1–2.3		D792-44T
Tensile strength at 77 F, psi	1,500–2,500	(1)	D638-44T
Elongation at 77 F, %	100–200		D638-44T
Flexural strength at 77 F, psi	2,000	(2)	D650-42T
Stiffness at 77 F, psi (0.125 in.)	60,000		D747-43T

Hardness, "D," Durometer	55–70		....
Compressive strength, psi, at 0.1% deformation	1,700		D695-42T
Deformation under load at 50 C under 1200 psi, % in 85 hr	4–8		D621-43
Heat-distortion temperature, low-load, °F	270		D648 (B)-44T
Specific heat, Btu/lb°F	0.25	(3)	
Coefficient of linear expansion per °F (77–140 F)	5.5×10^{-5}		D696-42T
Thermal conductivity, Btu/hr/ft²/°F in. (0.18 in.)	1.7	(4)	Arl. P-32
Dielectric strength, short-time, volt/mil (0.080 in.)	400–500	(5)	D149-40T
Surface arc-resistance, seconds	700	(6)	D495-42
Volume resistivity, ohm-cm	10^{15}		D257-38
Surface resistivity at 100% rel. humidity, megohms	3.6×10^{6}		D257-38
Dielectric constant at 60, 10^3, 10^6, 10^8 cycles	2.0–2.05		D150-40T
Power factor at 60, 10^3, 10^6, 10^8 cycles	0.0005		D150-40T
Water absorption, %	0.00	(7)	D570-42
Static coefficient of friction against polished steel	0.09–0.12	(8)	
Vapor pressure, mm Hg at 25 C	10^{-6}		
Outdoor weathering	No detectable change in 3 years		

(1) Tensile strength in oriented film may be as high as 15,000 psi. (2) Specimens do not break. (3) Method of mixtures. (4) Cenco-Fitch apparatus. (5) 1000–2000 volts/mil in thicknesses 5 to 12 mils. (6) Does not track. (7) Not wet by water unless a surface-active agent is added. (8) Inclined-plane method.

If the final product is to be rods, the extruded rods are hardened by immersion in dilute formaldehyde. If sheets are desired, the extruded rods are hot pressed in hydraulic presses, and the sheets so formed are hardened in formaldehyde. After they have hardened, the rods or sheets are carefully dried to a controlled moisture content, which may require weeks to months, depending on their size, diameter, or thickness.

This material is nonburning, has good resistance to organic solvents, and may be had in a wide range of colors. It is hygroscopic and affected by atmospheric moisture changes.

Casein plastics commercially known as Ameroid, Galorn, etc., are used in the manufacture of buttons, handles, small novelties, and trimming accessories.

ANILINE FORMALDEHYDE. This resin, known in the trade as Dilectene or Cibanite, is not to be classified as either a thermosetting resin or a thermoplastic resin. It will soften somewhat when heated, but it will not flow as do resins of the thermoplastic type. Under pressure, however, it may be caused to assume various shapes and forms when hot. The chemical stability of aniline formaldehyde resin is very good. Although it is attacked by strong acids, it is unaffected by alkalies and is not soluble in any of the common organic solvents; alcohol and aromatic hydrocarbons particularly have no effect on the material.

Table 7. Properties of Unfilled Aniline Formaldehyde Resin

Specific gravity	1.21
Tensile strength, psi	10,500
Flexural strength, psi	15,000
Modulus of elasticity in flexure, psi	510,000
Compression strength, psi	20,000
Impact strength (Izod), $1/2 \times 1/2$-in. specimen, parallel to molding pressure, ft-lb/in. of notch	0.33
Thermal expansion, in./in./°C	3×10^{-5}
Water absorption in 24 hr, $3 \times 1 \times 0.075$-in. specimen, %	0.08
Dielectric constant, 10^6 cycles	3.5
Power factor, 10^6 cycles	0.006
Cost, dollars/lb	2.00

The material is of a reddish brown color and can be dyed in dark colors only. It has found considerable use in high-frequency applications such as coil forms, vacuum tube sockets, and antenna housings. The resin, having good mechanical strength and a high order of insulation resistance, which is maintained under the influence of moisture and atmospheric conditions, is also employed for terminal boards, strips, and blocks. The properties of the material are given in Table 7.

11. THERMOSETTING PLASTICS

PHENOL FORMALDEHYDE MOLDING COMPOUNDS. These compounds, commercially known as Bakelite, Durez, Resinox, etc., are made when phenols react with formaldehyde in the presence of a catalyst to form the phenolic resin. The type of catalyst has a considerable influence on the properties of the resultant plastic. The base resin is ground and mixed with a lubricating agent and other materials to form a honey-colored resin compound. This resin is rather hard and brittle, and, in order to obtain satisfactory impact strength, fillers and pigments are added to achieve the desired properties and coloration.

The fillers influence the particular properties of the finished mixture. Listed below are a few of the common fillers and the type of application for which each is used. The materials, depending on the type of filler, have specific gravities ranging from 1.27 to 2.00, and the cost per pound varies from $0.15 to $0.61.

Filler	Application
Wood flour	General purpose
Cotton flock	Shock resistant
Shredded or chopped fabric	Shock resistant
Chopped canvas or twisted cord	Heavy impact
Inorganic fillers (Asbestos, silica, mica)	Low water absorption, good heat resistance, improved dimensional stability, and low thermal coefficient of expansion

Mica-filled molding compounds also exhibit excellent electrical properties, especially with regard to low dielectric loss.

Molded phenolics have good resistance to most solvents and to acid attack but are decomposed by strong alkalies. Because their coefficient of thermal expansion is greater than that of metals, inserts are held securely in molded parts as the material shrinks when cooled from molding temperature. Molded phenolics are used for such parts as clock cases, telephone equipment, radio cabinets, handles, electrical insulators, and vacuum tube sockets. Their properties are listed in Table 8.

Table 8. Approximate Physical and Electrical Properties of Molded Thermosetting Plastic Materials

Type	Tensile Strength, 1000 psi	Flexural Strength, 1000 psi	Impact at 77 F (Izod), ft-lb/in. of notch	Coefficient of Thermal Expansion, in./in./°C	Heat Resistance, continuous, °F	Dielectric Constant, 10^6 cycles	Power Factor, 10^6 cycles
General-purpose phenolic	5.5– 8.5	9.0–12.0	0.24–0.44	$3.0\text{–}4.5 \times 10^{-5}$	300	4.5–6.0	0.03 –0.06
High-impact phenolic	4.0– 9.0	8.0–15.0	2.0–8.0	$2.9\text{–}4.4 \times 10^{-5}$	240	4.5–6.0	0.03 –0.06
Low-loss phenolic	4.0– 7.0	8.0–12.0	0.30–0.38	$1.8\text{–}1.9 \times 10^{-5}$	275	4.0–5.0	0.005–0.03
General-purpose urea formaldehyde	6.0–13.0	10.0–16.0	0.20–0.35	$2.5\text{–}3.0 \times 10^{-5}$	170	6.6–7.7	0.027–0.035
General-purpose melamine formaldehyde	7.5–13.0	9.0–16.0	0.20–0.35	$2.0\text{–}4.5 \times 10^{-5}$	210	7.2–8.0	0.025–0.45
Fabric-filled melamine formaldehyde	8.0–11.0	11.0–17.0	0.6–1.4	$2.0\text{–}4.5 \times 10^{-5}$	250	6.1–6.9	0.040–0.065
Asbestos-filled melamine formaldehyde	5.5– 7.0	7.5–11.0	0.25–0.40	$2.0\text{–}4.5 \times 10^{-5}$	>250	6.7	0.041

Note: Procurement specifications: phenolic molding compounds—ASTM. D700; melamine formaldehyde molding compounds—ASTM. D704; urea formaldehyde molding compounds—ASTM D705.

UREA FORMALDEHYDE MOLDING COMPOUNDS. Urea formaldehyde molding compounds, commercially available as Beetle, Bakelite Urea, Plaskon, etc., are made when urea is compounded with formaldehyde in the presence of an alkaline catalyst such as sodium hydroxide. The filtered solution of urea formaldehyde in water is mixed with purified wood cellulose as a filler and dried. Acid or acid-producing catalysts, such as oxalic acid, are added to assist in the final polymerization.

The urea formaldehyde molding compounds are extremely color fast and readily take dyes or pigments. Except for dimensional stability, which is somewhat poorer than that of general-purpose phenolics, the physical and chemical properties of these materials are similar to those of phenol formaldehyde molding compounds having similar fillers. However, they exhibit good arc resistance and, unlike the colored phenolic compounds, can be made with a considerable degree of translucency. The specific gravity of the urea formaldehyde plastics varies from 1.45 to 1.55. The compounds cost from $0.22 to $0.65 per pound.

Urea formaldehyde molding compounds find typical applications in reflectors, clock and radio housings, instrument dials, closures, electrical parts, etc. The physical and electrical properties are given in Table 8.

MELAMINE FORMALDEHYDE MOLDING COMPOUNDS. Melamine formaldehyde molding compounds, commercially available as Melmac, Plaskon, Catalin, Resimene, etc., are prepared by compounding melamine, a complex organic material fabricated from calcium carbide, nitrogen, and formaldehyde. The melamine formaldehyde resin resulting is then dried and is filled with either purified wood cellulose or fabric fillers. The materials have a specific gravity of 1.45 to 1.55 and cost from $0.38 to $0.55 per pound.

These compounds, like the urea compounds, have high arc resistance but excel the ureas in hardness, are more heat resistant, show greater resistance to dilute acids and alkalies, and are less affected by boiling water.

Typical commercial applications of the melamine formaldehyde molding compounds are in the manufacture of terminal blocks, aircraft ignition parts, circuit breakers, tableware, etc. Their properties are given in Table 8.

CAST PHENOLICS. The bulk of cast phenolics is produced in the form of sheets, rods, and tubes. Trade names are Bakelite cast resinoid, Catalin, Marblette, Crystle, Prystal, etc. The finished articles are fabricated by machining and polishing. They are available in an unlimited range of color, both opaque and transparent. In addition to the stock forms, custom-made castings are produced in almost any shape desired. These are cast by hand-pouring the specially prepared, partially resinified mass into a mold and allowing it to stand for a few hours to several days, depending on the temperature and catalyst. With large castings, longer curing times are required. Usually the dimensional stability of cast phenolics is not so good as that of molded products, for resinification continues within the plastic over a considerable period of time, resulting in volume changes.

Typical applications of cast phenolics are personal accessories, hardware, display fixtures, toys, etc. Special castings are made in the production of small radio cabinets.

12. LAMINATED PLASTICS

HIGH-PRESSURE LAMINATES. The fundamental difference between thermosetting laminated plastics and molded plastics is in the nature of the filler which, to a great extent, determines the properties of the laminate. The fibrous sheets principally employed for these purposes are of paper, cotton fabric, canvas duck, asbestos paper and fabric, glass cloth, and glass fibers. In general, synthetic resins of the phenol formaldehyde type are most widely used, although urea formaldehyde and melamine formaldehyde resins are also employed. In some cases, in order to produce materials for certain applications, combinations of the three resins are required. The resin is used in the form of a varnish in solvents or in water.

In the production of the laminates, the fibrous sheets are passed through a bath of varnish, the excess resin is squeezed out either by rolls or by a doctor blade, and the sheets are then passed through a heated oven in which the solvents are evaporated and the resins are partially cured. The viscosity of the resin solution and the setting of the squeeze rolls or doctor blades are carefully controlled to give the desired resin content in the impregnated filler sheets. In the drying operation, the volatile content of the treated filler sheets must also be closely controlled so that the resin solubility and residual flow is sufficient to obtain a good bond in the subsequent pressing operation.

The impregnated stock thus produced is manufactured into sheets, tubes, rods, and special shapes. When sheets are made, the impregnated material is cut into sheets of the desired length, placed in stacks between polished or otherwise treated plates to give varied surface textures, and subjected to heat and pressure in a hydraulic press.

To produce tubes, the impregnated material is wound over a mandrel the size of the inside diameter of the finished tube and either baked in an oven to produce a rolled tube or formed in a mold under heat and pressure if a molded tube is desired. The manufacture of molded rods also starts by winding the impregnated material on a mandrel with a very small diameter. The mandrel is withdrawn before the curing operation is performed in a closed mold. Rods are also molded by placing strips of the impregnated stock in a closed mold and applying pressure edgewise, causing the laminations to crinkle. Rods may also be turned from sheet stock.

The laminated thermosetting plastics, which are known commercially as Formica, Micarta, Synthane, Textolite, Dilecto, Panelyte, Spauldite, Phenolite, etc., are essentially used as structural members or electrically insulating parts. They are employed for such applications as automotive timing gears, insulation in keys, jacks, relays, and other electrical mechanisms, diaphragms for loudspeakers, bearings, helmets, panels, refrigerator door parts, nameplates and dials, counter tops and paneling, coil forms, and terminal strips.

Generally speaking, 225 F is the maximum safe continuous operating temperature for any of the paper- and fabric-base materials. The asbestos-base grades may be used at temperatures of the order of 250 to 300 F. Table 9 shows the physical properties of the various laminated phenolic materials.

Table 9. Physical Properties of the Various Laminated Phenolic Materials

Filler	Tensile Strength, 1000 psi	Flexural Strength, 1000 psi	Compressive Strength, 1000 psi	Water Absorption in 24 hr (max), 3 x 1 x 1/16 in. sample, %	Edgewise Impact Strength (Izod), at 77 F, ft-lb/in. of notch	Specific Gravity	Linear Thermal Expansion 10^{-5} in./in./°C

LOW-PRESSURE AND NO-PRESSURE LAMINATES. Low-pressure laminating is chiefly a wartime development brought about by the need for large sections of plastic laminate, of high strength, molded in shapes too complicated for high-pressure techniques. The low-pressure laminates can be cured by the application of heat at pressures generally below 250 psi, using inexpensive molds made from plaster of Paris, wood, lightweight sheet metal, etc.

A great deal of interest has also been shown in the construction of laminates prepared by the application of slight or no pressure, with or without heat. The pressure in most cases need only be sufficient to exclude air pockets. The resins used to manufacture these laminates are called contact resins and are usually furnished in the form of viscous, partially condensed, unsaturated fluids.

In the production of some of the low-pressure and no-pressure laminates, resins such as unsaturated polyesters, phenolics, modified melamine formaldehyde, allyls, cellulose acetate and ethyl cellulose are used.

The type of filler used in the construction of these laminates is also of great importance in obtaining adequate strength properties. Such fillers may be veneers or thin plies of wood, high-strength paper, woven fibers of cotton, or glass filaments used either in felted form or woven into fabric. Laminates made with glass fabrics possess an exceptionally high strength-weight ratio.

The foregoing laminates are employed for such items as aircraft rudders, doors, gasoline tanks, wall panels, instrument cases, luggage, buckets, ducts, boats, and decorative applications.

POST-FORMING LAMINATED PHENOLIC PLASTICS. A special laminated forming sheet has been developed by several manufacturers of laminated plastic sheet. The material generally used has been a special grade of phenolic resin-laminated canvas. Normally the use of laminated phenolics has been limited to shapes that can be derived from simple forms, such as plates, rods, tubes, angles, and channels. Forms more intricate than these have always required expensive steel molds. With the new material, forming is accomplished by heating the sheet rapidly to a high temperature (below the blistering point), quickly bending or drawing it into the new contour, and holding it in this shape until it has cooled. Common heating methods are (1) parallel hot plates, (2) infrared radiant heat, (3) hot-air ovens, and (4) dielectric heating.

The molds for this type of laminate may be made from wood, high-pressure laminates, Masonite die stock, or concrete. In large production jobs, where the number of pieces

may run into thousands, blanking dies of steel or Kirksite (cast zinc alloy) are sometimes provided.

The post-forming material used during World War II to manufacture numerous aircraft components is now being adapted to the production of many commercial items.

SANDWICH CONSTRUCTIONS. These materials consist of thin-gage, high-strength surface sheets, bonded to low-density cores by means of waterproof, high-strength synthetic adhesives. They are finding application as structural and nonstructural members of boats, aircraft, furniture, refrigerators, and other items requiring high-strength, lightweight materials. The surface sheets or skins furnish rigidity and strength to the structure and are made of such materials as stainless steel, aluminum, magnesium, and high- and low-pressure plastic laminates using glass fiber, paper, duck, or wood as the filler sheets. Balsa wood was first used as a core material, but expanded (porous) plastics are now used for this purpose. Cellular cellulose acetate Strux CCA, expanded polystyrene Styrofoam, expanded phenolic resin Textolite Foam, expanded rubber Flotofoam, Cell-tite, and expanded polyvinyl formal Plastazote are some of the most widely used plastics for core materials. The rigid plastic foams weigh from 1.5 to 30 lb per cu ft.

In addition to the expanded plastic cores, a honeycomb core is sometimes used in sandwich constructions. The core is made from resin-impregnated sheet material which has been cured and assembled into the form of nested hexagonal-shaped cells resembling bees' honeycomb.

Scientists are endeavoring to develop the stiffest and lightest material to fill the wings on superspeed planes (over 750 mph).

PLASTICS PRODUCTION. Relative output of the various types of plastics and synthetic resins is indicated in Table 10.

TRADE NAMES. A partial list of trade names of plastics materials appears in Table 11. For a complete directory of trade names of plastics materials see *Modern Plastics Encyclopedia*, published by Plastics Catalogue Corporation, 122 East 42 St., New York 17, N. Y.

Table 11. Trade Names of Plastic Materials

Type of Composition	Trade Name
Phenol formaldehyde	Bakelite, Catalin, Co-ro-lite, Crystle, Durez, Durite, Dilecto, Formica, Insurok, Lamicoid, Micarta, Marblette, Makalot, Phenolite, Panelyte, Resinox, Spauldite, Synthane, Textolite
Urea formaldehyde	Bakelite Urea, Beetle, Plaskon, Uformite
Melamine formaldehyde	Catalin, Melmac, Plaskon, Resimene
Analine formaldehyde	Cibanite, Dilectene
Cellulose nitrate	Celluloid, Nixon CN, Nitron, Pyralin
Cellulose acetate	Bakelite C.A., Chemaco C.A., Fibestos, Lumarith, Nixon CA, Plastacele, Tenite I
Cellulose acetate butyrate	Tenite II
Cellulose propionate	Forticel
Ethyl cellulose	Chemaco E.C., Ethocel, Lumarith E.C., Nixon E.C.
Polyvinyl chloride	Geon, Koroseal
Polyvinyl alcohol	Resistoflex, PVA
Polyvinyl chloride acetate	Vinylite, Tygon
Polyvinyl butyral	Butacite
Polyvinylidene chloride	Saran
Methyl methacrylates	Lucite, Plexiglas
Polymeric amides	Nylon
Polystyrene	Styron, Loaline, Lustron, Bakelite Polystyrene
Styrene copolymers	Textolite 1421, Textolite 1422, Plexene M, Styraloy 22
Unsaturated polyesters (cross-linked addition polymers)	Laminac, Selectron, Thalid, Paraplex
Polyethylene	Polythene, Bakelite Polyethylene
Polytetrafluorethylene	Teflon
Trifluorochloroethylene	Kel-F
Casein	Ameroid, Galorn

REFRACTORIES

By J. Spotts McDowell

Refractories are structural materials used at high temperatures in industrial furnaces. They are supplied mainly in the form of brick of standard sizes and of special shapes. Refractories also include refractory cements, bonding mortars, plastic firebrick, castables, ramming mixtures, and other bulk materials such as dead-burned grain magnesite, chrome ore, ground ganister and special clays.

The types of refractory brick most generally used are fireclay, superduty fireclay, high alumina, silica, magnesite, magnesite chrome, chrome, chrome magnesite, and forsterite brick and insulating firebrick of various classes. Other refractory products, such as silicon carbide, sillimanite, and zirconia, usually referred to as special refractories, are marketed in relatively smaller tonnages. With the exception of silicon carbide, they are not discussed in this chapter.

The life of refractories is affected by the high temperatures to which they are subjected and usually by one or more of the following influences: abrasion, corrosion through chemical action of slags and fluxes, erosion by mechanical action of molten metal or slag or by dust-laden gases moving at high velocity, spalling of various types, or the chemical or physical effect of various gases or fumes.

13. TYPES OF REFRACTORIES

FIRECLAY BRICK. Of all the various types of refractories, the most widely used are fireclay brick, made from flint and plastic fireclays. Hydrous aluminum silicate minerals, of which kaolinite is the most common, are the essential components of fireclay. The theoretical analysis of kaolinite, free from accessory components, is 39.5% alumina, 46.5% silica, and 14% water. At high temperature the water is driven off, and the resulting calcined material theoretically contains 45.9% alumina and 54.1% silica. However, chemical analyses of even the purest clays disclose the presence of small amounts of other compounds, such as those of iron, calcium, magnesium, and titanium, as well as alkalies, and usually free silica.

Flint clays, known also as hard clays, are hard and dense and break with a conchoidal fracture. After they are ground and mixed with water, their plasticity and drying shrinkage are very low; their firing shrinkage is somewhat variable and moderately low. Flint clays possess high refractoriness. Deposits of flint clay of considerable commercial importance occur in rather limited areas in central Pennsylvania, Maryland, eastern Kentucky, southern Ohio, and eastern Missouri.

Plastic and semiplastic clays cover a wide range in refractoriness, plasticity, and bonding strength. Their shrinkage during drying and firing is fairly high. Many of these clays have high plasticity and excellent bonding power.

White-burning clays are generally known as kaolins. Pure kaolins usually are only moderately plastic, but their drying and firing shrinkages are high. However, kaolins that contain appreciable amounts of free silica have low drying and firing shrinkages. Some of the largest deposits of kaolin in America are found in Georgia. Kaolins suitable for the manufacture of refractories are found also in various other states.

Most standard sizes of fireclay brick are made by machine, by either the power-press or the extrusion process. The power-press process comprises (1) grinding the clays in a dry pan, (2) screening them to desired sizes, (3) blending and thoroughly mixing them with a small but definitely controlled amount of water, and (4) forming the brick under high pressure by means of a mechanically operated press.

The steps in the manufacture of brick by the extrusion process are (1) grinding the clay or clays in a dry pan, (2) screening and blending them and tempering them with a controlled amount of water in a mixer, (3) extruding the tempered clay through a die as a column, (4) cutting the column of clay into desired sizes by means of wires, and (5) pressing the sizes mechanically to form brick with sharp corners and edges and smooth surfaces.

Special shapes are generally made by hand. The process consists in (1) grinding a single clay or a mixture of clays with water in a wet pan and (2) molding the brick by hand. A relatively small proportion of standard sizes is made by hand. After being molded and partially dried, these brick are re-pressed in a hand-operated press.

The brick formed by any of the processes described are dried either on hot floors or in tunnel driers, after which they are fired in periodic downdraft kilns or in continuous car-type tunnel kilns.

To meet certain requirements, brick are manufactured by a method in which a high vacuum is applied during the forming operation. In the extrusion process, the method is called de-airing. As applied to the power-press process, it is known as vacuum pressing. Brick so made are harder, stronger, less porous, and slightly heavier than brick made otherwise.

Fireclay Brick have been classified as follows by the American Society for Testing Materials (ASTM C27-41):

Superduty Fireclay Brick. A fireclay brick having a pyrometric cone equivalent (see p. 5-53) not lower than cone No. 33 on the fired product, not more than 1% linear shrinkage in the linear change test, schedule C (2910 F, 1600 C), and not more than 4% loss in the panel spalling test (preheated at 3000 F, 1650 C).

High-heat Duty Fireclay Brick. A fireclay brick conforming to one of the following requirements: pyrometric cone equivalent not lower than cone No. 31-32, or not more than 1.5% deformation in the 2460 F (1350 C) load test.

Intermediate-heat Duty Fireclay Brick. A fireclay brick conforming to one of the following requirements: pyrometric cone equivalent not lower than cone No. 29, or not more than 3% deformation in the 2460 F (1350 C) load test.

Low-heat Duty Fireclay Brick. A fireclay brick having a pyrometric cone equivalent not lower than cone No. 19.

HIGH-ALUMINA BRICK. Brick of the alumina-silica group of refractories containing more than 47.5% alumina are known as high-alumina refractories. The raw materials used in their manufacture include diaspore, diaspore clays, bauxite, kyanite, andalusite, sillimanite, and crystalline alumina or corundum. Some of these materials are used singly; others are combined or blended with clays or other bonding agents, depending on the properties and the percentage of alumina desired in the finished product. High-alumina brick are made by processes similar to those used in the manufacture of fireclay brick.

High-alumina brick serve advantageously in place of superduty and high-heat duty fireclay brick under service conditions beyond the safe working limits of brick of those classes.

Various grades of high-alumina brick are available in the commercial classes containing approximately 50, 60, 70, 80, 90, and 99% alumina. Brick made mainly from diaspore clay have been classified as follows by the American Society for Testing Materials (ASTM C27-41):

50% Alumina-diaspore Fireclay Brick. Refractory brick having diaspore or nodular fireclay as an essential original ingredient, an alumina content of 50 ± 2.5%, and a pyrometric cone equivalent not lower than cone No. 34.

60% Alumina-diaspore Fireclay Brick. Refractory brick having diaspore or nodular fireclay as an essential original ingredient, an alumina content of 60 ± 2.5% and a pyrometric cone equivalent not lower than cone No. 35.

70% Alumina-diaspore Fireclay Brick. Refractory brick having diaspore as an essential original ingredient, an alumina content of 70 ± 2.5%, and a pyrometric cone equivalent not lower than cone No. 36.

SILICA BRICK. Quartzite rock, commonly referred to as ganister, is the raw material used in the manufacture of most silica brick. It is a hard, fine-grained rock, containing 97 to 98% silica. The steps in the manufacture of silica brick are (1) crushing and grinding the ganister in a unit known as a wet pan with the addition of water and approximately 1.75 to 3% lime, (2) molding in a power press or by hand; (3) drying in tunnel driers; and (4) firing, either in periodic downdraft kilns or in continuous car-type tunnel kilns. In a modified process, the ganister is ground in a dry pan, screened to definite sizes, and stored in bins. The separate sizes are later blended in desired proportions and mixed with water and approximately 1.75% to 3% lime. Molding, drying, and firing follow in order, as already outlined.

The lime added to the charge serves as a bond. During firing, it reacts with a portion of the quartzite and gives strength to the finished product.

During the firing operation, a permanent expansion of the brick takes place. Silica brick show a slight permanent expansion in high-temperature service, since it is not practicable to carry the permanent expansion to completion during the firing. The linear thermal expansion of well-burned silica brick amounts to 1.2 to 1.6%, the greater part of which occurs below 1200 F.

When silica brick is laid, it is important to provide for the reversible thermal expansion of about $^{3}/_{16}$ in. per ft. Since the joints take up some expansion, it is customary to allow for expansion at the rate of $^{1}/_{8}$ in. per ft. Expansion joints should be kept free from mortar by packing them with a filler which will burn out.

Silica brick are sensitive to rapid changes in temperature below 1200 F and should therefore be heated and cooled slowly between 1200 F and atmospheric temperature.

Three classes of silica brick are available (1) superduty silica brick, containing not more than 0.5% alumina, titania, and alkalies; (2) brick which might well be called high-heat duty silica brick, containing a total of about 0.9 to 1.25% alumina, titania, and alkalies, and (3) sandrock silica brick, containing a total of approximately 1 $^{1}/_{2}$ to 2 $^{1}/_{2}$% alumina, titania, and alkalies.

MAGNESITE BRICK. The outstanding characteristics of magnesite brick are their strongly basic chemical behavior and their extremely high refractoriness. Prior to 1939, practically all magnesite refractories were made from a rock which consists almost entirely of the mineral magnesite (magnesium carbonate). The large deposits of crystalline magnesite in Europe, in Manchuria, and in the state of Washington supplied by far the larger portion of all the magnesite used for refractory purposes. Natural magnesite is still used for the production of the major portion of the refractory magnesia employed in industry. The rock consisting of the mineral brucite (magnesium hydroxide), mined in Nevada, is used to a minor extent. A substantial amount of magnesium hydroxide is recovered from natural brines, such as seawater, bittern from salt works, and brine from deep wells.

The first step in the manufacture of magnesite brick is the firing of the raw material at high temperature in a rotary kiln. In the firing process, the carbon dioxide or the water of combination, as the case may be, is expelled, and practically complete shrinkage of the magnesia is effected. The product, known as dead-burned magnesite, is inert to atmospheric moisture and carbon dioxide gas.

For refractory purposes, dead-burned magnesite is supplied in the form of brick, of finely ground material for brick laying, and of granular material (dead-burned grain magnesite or magnesite ramming mixtures) for making and repairing furnace bottoms.

To make magnesite brick, the dead-burned magnesite is ground, mixed with a controlled amount of water, and molded at high pressure in a power press. Special shapes are molded by hand. The molded brick are thoroughly dried in tunnel driers and fired at extremely high temperature under a controlled time-temperature schedule in downdraft periodic kilns or in continuous car-type tunnel kilns.

Grain magnesite, which is widely used for the construction of monolithic furnace hearths, consists of a mixture of granules, varying in size from about $^{5}/_{8}$ in. in diameter to particles of extreme fineness. It is fritted into place in thin layers by the application of heat. Magnesite ramming mixtures having a maximum particle size of about $^{1}/_{4}$ in. in diameter are rammed into place with air hammers and take a strong set merely upon drying.

CHROME BRICK. The raw material in the manufacture of chrome brick is a rock known as chrome ore. The composition of ores suitable for the manufacture of refractories ranges from 30 to 50% chromic oxide (Cr_2O_3), 12 to 18% ferrous oxide (FeO), 13 to 18% magnesia (MgO), 13 to 32% alumina (Al_2O_3), and 4 to 8% silica (SiO_2). In the manufacture of chrome brick the ore is ground, properly sized, mixed with a small amount of water, and molded under heavy pressure. The molded brick are dried and then fired at high temperature.

MAGNESITE-CHROME AND CHROME-MAGNESITE BRICK. It has been demonstrated that brick with properties superior for various purposes to those made from magnesite alone or from chrome ore alone can be manufactured from compositions consisting of blends of chrome ore and dead-burned magnesite in suitable proportions. The two-component brick made from such blends are known as magnesite-chrome brick and chrome-magnesite brick; in each case, the principal component is named first. In general, these two-component brick have superior resistance to spalling and superior rigidity at high temperature under load. Such brick are usually bonded chemically instead of by firing.

However, one type of chrome-magnesite brick is bonded by firing at extremely high temperature.

METAL-ENCASED BRICK. Thin sheets of steel in the joints between certain types of basic brick add materially to their life by decreasing their tendency to spall and by increasing their rigidity at furnace operating temperatures.

With straight, arch, wedge, and key brick and with brick of certain special shapes, steel is applied in the form of a casing which covers three or four faces of the brick. Other metal-encased brick consist of basic refractory material packed solidly in steel tubes 3 in. in diameter and 9, 13 1/2, or 18 in. long. The materials most generally used with steel casings are fired magnesite brick and chemically bonded magnesite and magnesite-chrome brick.

FORSTERITE BRICK. The mineral forsterite is a silicate of magnesium, having the theoretical chemical formula $2MgO \cdot SiO_2$, corresponding to a composition of 51.3% magnesia and 42.7% silica. The melting point of pure forsterite is 3470 F. In the United States, forsterite brick were first manufactured commercially in 1933.

In nature, forsterite rarely occurs in pure form but is usually associated with a silicate of iron known as fayalite ($2FeO \cdot SiO_2$), in the mineral olivine. A low-iron olivine rock known as dunite is the raw material from which forsterite brick are made.

Accessory minerals which occur with the olivine are converted into additional forsterite through reaction with magnesia added during the process of manufacture. The brick are molded principally by the power-press process under extremely high pressure. The required firing temperature is higher than that necessary for most other refractory materials.

INSULATING FIREBRICK. The primary function of furnaces built of refractory materials is to confine and to utilize heat energy. The quantity of heat which passes through furnace walls, to be dissipated into the surrounding air, often constitutes a considerable proportion of the total heat input. Such heat losses may be reduced greatly by the application of insulating firebrick to the outer faces of the refractory walls.

In intermittently operated furnaces, the heat required to bring the furnace to operating temperature is lost when the furnace is permitted to cool. This heat loss is often of greater significance in the heat balance than is the amount of heat necessary to maintain the required temperature for the few consecutive hours of operating time. Because of their light weight, insulating firebrick have low heat capacities. Consequently their use in intermittently operated furnaces reduces not only the amount of heat lost by conduction and radiation, but also the amount of heat stored in the brickwork, which is lost when the furnace is cooled to atmospheric temperature.

Insulating firebrick have been classified by the American Society for Testing Materials (ASTM C155-47) as indicated in Table 1. The grouping of insulating firebrick in accordance with Table 1 is based on bulk density (weight per cubic foot) and the behavior in the reheat change test conducted at the specified temperature.

Table 1. Grouping of Insulating Firebrick

Group Identification	Permanent Linear Change * Not More than 2% When Tested at	Bulk Density Not Greater Than
16	1550 F (845 C)	34 lb/cu ft
20	1950 F (1065 C)	40 lb/cu ft
23	2250 F (1230 C)	48 lb/cu ft
26	2550 F (1400 C)	52 lb/cu ft
28	2750 F (1510 C)	60 lb/cu ft

* Maximum temperature held 24 hr in accordance with Standard Method of Reheat Change of Insulating Fire Brick, ASTM C210-46.

MORTAR MATERIALS. The two classes of mortar materials for refractory brick masonry are (1) hot-setting bonding mortars shipped in dry form and (2) cold-setting bonding mortars shipped in either dry or wet form. Each class includes materials of various compositions, each of which has a definite field of application. The bonding strength of hot-setting bonding mortars is developed only at high temperatures, with the formation of what is known as a ceramic bond. These mortars include such materials as finely ground fireclay, silica, high-alumina, magnesite and chrome ore, and forsterite, as well as a great variety of blends of the different commercially available refractory materials. Cold-setting bonding mortars are distinguished by their ability to take a rigid cold set and to form a strong bond at atmospheric temperature. These mortars are similar in composition to those of the hot-setting class, but in their preparation chemical bonding agents are added which impart cold-setting properties.

The type of refractory brick to be bonded and the service conditions to which they will be exposed govern the selection of the mortar material best suited to meet the requirements.

PLASTIC FIREBRICK. Plastic firebrick is made from blended raw materials of various compositions. It is supplied in standard and superduty qualities, ready mixed, with just a sufficient amount of water to render it suitable to be rammed into place. It serves admirably for emergency repairs and under certain conditions may be used for forming complete one-piece furnace linings.

CASTABLES. Castables are refractory materials of various compositions, supplied in dry form, which require thorough mixing with water to be suitable for casting. The ease with which castables can be applied and the fact that they quickly develop a strong bond make them useful where time is important for such applications as linings of irregular dimensions in small furnaces, patching, and the production of intricate special shapes. Castables are adapted for the construction of baffles, stoker installations, oil burner blocks and ports, door linings, ash-pit linings, and domestic oil-fired furnace linings. The three available classes of castables are standard, superduty, and lightweight.

RAMMING MIXTURES. Ramming mixtures consist essentially of ground refractory materials of graded particle size, mixed with small amounts of other ingredients to give good working qualities and a cold set. Various of these mixtures have a chrome or a magnesite base. They are available in both dry and plastic forms.

Upon air-drying, ramming mixtures set to form a strong, dense, well-bonded refractory. The strength and density may increase at high temperatures. Their principal application is in the bottoms and hearths of furnaces, lining of ladles and converters, roofs and linings of small electric furnaces, burner blocks, and various other constructions.

SILICON CARBIDE REFRACTORIES (data supplied by The Carborundum Company, Refractories Division, Perth Amboy, N. J.) Silicon carbide is composed of carbon and silicon, the chemical formula being SiC. It is made in the electric resistance furnace. The crystalline product is generally considered to form at approximately 3350 F or higher and to dissociate at approximately 4050 F, below which temperature no softening or fusion occurs. Its hardness is 9.6 on the Moh scale, giving a remarkable resistance to abrasion. It is inert to most acids, liquid or gaseous, but may be decomposed by alkali when subjected to high temperature. Silicon carbide reacts with basic slags and molten iron and steel. It is made into refractory brick and shapes varying widely in size, weight, design, etc.

Silicon carbide refractories comprise silicon carbide crystals bonded with small percentages of permanent binders of which there are many, depending on the type of service. The standard 9 by $4\frac{1}{2}$ by $2\frac{1}{2}$-in. brick weighs approximately 9.25 lb. Many different special shapes are made for boilers, heat-treating, malleable-iron-annealing, forge, and melting furnaces, soaking pits, regenerators, electric furnaces, zinc retorts, coking and calcining retorts, gas producers, water gas generators, porcelain enameling furnaces, periodic and tunnel kilns, glass lehrs, rotary kilns, roasting furnaces, etc. Silicon carbide refractories are especially resistant to the destructive action of clinker formed from coal ash. Thermal conductivity of the higher grades of silicon carbide refractories averages 108 Btu per sq ft per inch of thickness per °F per hr in the temperature range 1200 to 2800 F, making them suitable for indirect heating, as in muffles, retorts, recuperators, regenerators, etc. Other physical properties are: modulus of rupture at 2462 F, 900 to 6250 psi; crushing strength at 2462 F 10,000 to 15,000 psi; at 68 F, 15,000 to 20,000 psi. The mean specific heat in the range 0 to 2552 F is 0.285. Silicon carbide refractories are characterized by extremely high spalling resistance.

14. PROPERTIES OF REFRACTORY BRICK

ABRASION. As applied to refractory brick, abrasion is defined as "wearing away of refractory surfaces by the scouring action of moving solids." (*The Standard Definitions of Terms Relating to Refractories*, ASTM C71-47.)

In certain types of furnaces, as, for example, in shaft lime kilns, the refractory linings are subjected to more or less severe abrasion by moving charges. The sandblast action of hot dust-laden gases impinging upon refractories (furnace walls) is another example of abrasive action.

Tests have been developed which indicate clearly the relative resistance of cold brick to abrasion. These tests, however, do not measure the resistance to abrasion of brick at furnace operating temperatures. No entirely satisfactory method has been devised for evaluating the resistance of hot brick to abrasion. However, brick which are mechanically strong at a given operating temperature will usually be resistant to abrasion.

CHEMICAL COMPOSITION. (See Tables 2 and 3.) The compositions of the different types of refractories vary considerably. For Chemical Analysis of Refractory Materials, see ASTM C18-45, *Manual of American Society for Testing Materials, Standards on Refractory Materials*, 1948.

Table 2. Typical Chemical Compositions of Alumina-silica Refractories

	Composition, %			
Type and Class of Brick	SiO_2	Al_2O_3	TiO_2	Accessory Oxides
Fireclay				
Superduty	49–53	40–44	2.1–2.5	3–4
High-heat duty (aluminous)	52–60	35–40	1.8–3.3	2–6
High-heat duty (siliceous)	65–75	20–30	1.0–2.0	2–4
Intermediate heat duty	60–65	30–36	1.8–2.1	4–7
High-alumina				
50% alumina class	41–47	47.5–52.5	2.2–2.9	3–4
60% alumina class	31–37	57.5–62.5	2.2–3.5	3–4
70% alumina class	20–26	67.5–72.5	3.2–4.0	3–4
80% alumina class	10–16	77.5–82.5	3.0–4.0	3–4
90% alumina class	8–9	89–91	0.5–0.8	0.5–1.0

Table 3. Typical Chemical Compositions of Silica and Basic Refractories

	Composition, %						
Type of Brick	Al_2O_3	SiO_2	CaO	MgO	FeO	Fe_2O_3	Cr_2O_3	Accessory Oxides
Silica		95–97	1.8–3.0					0.5–2.5
Magnesite (fired)				83–93		2–7		5–10
Chrome (fired)	15–33	3–6		14–18	11–17		30–45	
Forsterite		33–40		47–53		9–11		3–4

COLD CRUSHING STRENGTH. (See Table 4.) This property provides little or no indication of the strength at furnace operating temperatures. However, if the cold strength is extremely low, the brick may not withstand handling and shipping without excess scuffing and breakage. For details, see *Standard Method of Test*, ASTM C133-39.

Table 4. Cold Crushing Strength of Refractories

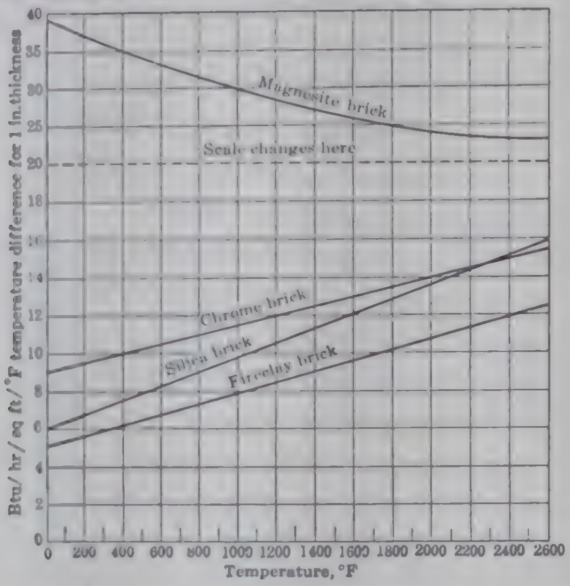
Type of Refractory	Cold Crushing Strength, 9-in. brick set on end, psi
Fireclay	
Superduty	900–4000
High-heat duty (handmade)	700–2500
High-heat duty (machine-made)	1000–6000
Intermediate-heat duty	1200–6000
High alumina	
50% alumina class	2500–5000
60% alumina class	1800–6000
70% alumina class	4000–6000
80% alumina class	5000–8000
90% alumina class	4000–7000
Silica	2000–4000
Magnesite	2000–10000
Magnesite-chrome (chemically bonded)	2000–4000
Chrome	2000–6000
Chrome-magnesite (chemically bonded)	2000–4000
Forsterite	1500–4000

THERMAL CONDUCTIVITY. Table 5 gives the approximate thermal conductivities of refractories over a wide range of temperatures. For details of *Standard Method of Test*, see ASTM C182-47, also C201-47 and C202-47.

Table 5. Approximate Thermal Conductivities of Refractories

(Btu/hr/sq ft of wall area, per °F temperature difference, for 1-in. thickness)

(From *Modern Refractory Practice*, 2nd ed., Harbison-Walker Refractories Co., Pittsburgh, Pa., 1937 by permission.)



Kind of Brick	Temperature, °F													
	0	200	400	600	800	1000	1200	1400	1600	1800	2000	2200	2400	2600

REVERSIBLE THERMAL EXPANSION. The reversible linear expansion of various types of refractory brick is given in Fig. 1. The curves represent average values from atmospheric temperatures to the temperature indicated.

LOAD RESISTANCE AT HIGH TEMPERATURE. In high-temperature service, refractories may be subjected to heavy pressure due to arch stresses or to the weight of overlying courses of brickwork. Fireclay refractories are least resistant to load at high temperature. They are strong and rigid up to 2000 F. However, at 2250 F and under a load of 25 psi, high-heat duty fireclay brick exhibit slow plastic deformation which increases with rising temperature. Silica brick remain strong and rigid almost up to their temperature of failure. High-alumina brick up to those of the 70% alumina class show appreciable subsidence in the standard load test at 2462 F, as can be seen from Table 6. Basic brick

Table 6. Behavior of Refractory Brick under Load at High Temperature

Type of Brick	Linear Subsidence at 25 psi and 2460 F,* %	Temperature of Failure at 25 psi, °F
Fireclay		
Superduty	2–6	
High-heat duty (aluminous)	3–10	
High-heat duty (siliceous)	2–4	
High alumina (70% alumina class)	0.5–4	
Silica		2900–3100
Magnesite		2450–2800
Magnesite-chrome		2750–3000
Chrome		2450–2800
Chrome-magnesite		2750–3000
Forsterite		2700–3100

* See ASTM C16-41.

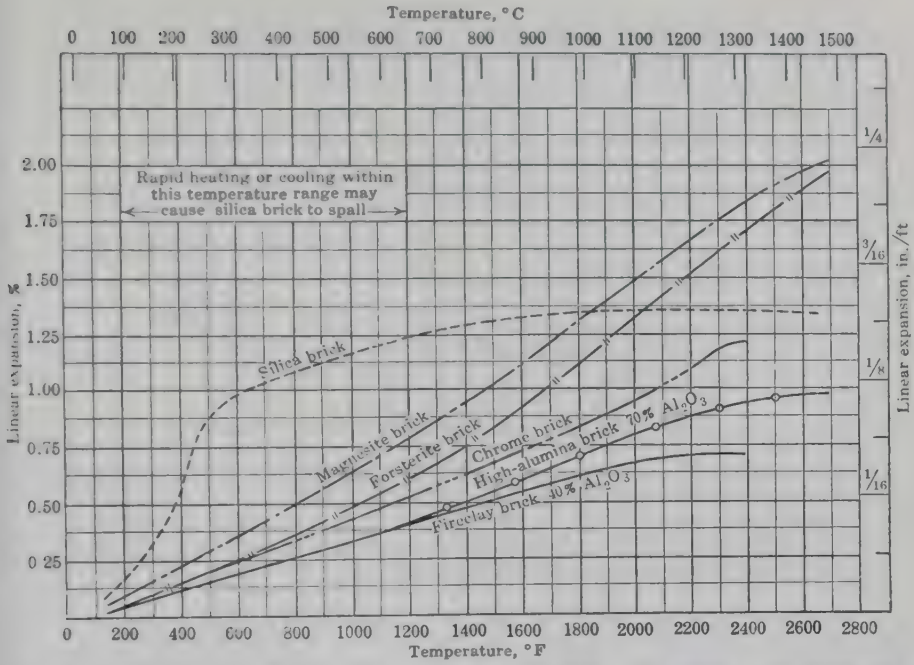

Fig. 1. Approximate reversible thermal expansion of refractories. To convert linear percentage of expansion into thirty-seconds of an inch per foot, multiply by 3.8. (Reproduced by permission from *Modern Refractory Practice*, 2nd ed., Harbison-Walker Refractories Co., Pittsburgh, 1937)

of various brands show wide variation in their behavior under load at high temperature. In general, they do not show plastic flow under load but fail abruptly.

MODULUS OF RUPTURE (see Table 7). The modulus of rupture of refractory brick is indicative only of their strength at atmospheric temperature and provides little or no indication of their strength at furnace operating temperatures. It is determined in accordance with *Standard Method of Testing*, ASTM C133-39.

Table 7. Modulus of Rupture at Atmospheric Temperature

Type of Brick	Modulus of Rupture, psi
Fireclay	
Superduty	600–1500
High-heat duty (handmade)	400–1500
High-heat duty (machine-made)	400–2000
Intermediate-heat duty	600–2200
High alumina	
50% alumina class	1000–1500
60% alumina class	600–1600
70% alumina class	1200–1500
80% alumina class	1500–2000
90% alumina class	1200–1400
Silica	400–1200
Magnesite	750–3000
Chrome	900–2000
Forsterite	450– 800

POROSITY (see Table 8). The porosity of refractory brick is related to their permeability, rigidity under load at high temperature, thermal conductivity, resistance to abrasion, and resistance to slag action. Low porosity is extremely important for brick used in contact with molten slag.

PYROMETRIC CONE EQUIVALENT. Pyrometric cone equivalent, as applied to refractories, is defined as the number of that standard cone whose tip would touch the supporting plaque simultaneously with that of a cone of the material being investigated, when tested in accordance with the standard method of test for pyrometric cone equivalent (PCE) of refractory materials. The determination of PCE consists in testing cones of

Table 8. Porosities by Volume, Average Values

(See *Standard Methods of Test*, ASTM C20-46.)

Type of Brick	Porosity, %
Fireclay	
Superduty	12–26
High-heat duty (handmade)	20–30
High-heat duty (machine-made)	12–27
Intermediate-heat duty	10–30
High alumina	
50% alumina class	13–25
60% alumina class	17–25
70% alumina class	23–33
80% alumina class	20–27
90% alumina class	21–26
Silica	22–30
Magnesite	18–24
Chrome	19–24
Chrome-magnesite	18–22
Forsterite	18–27

the ceramic material by comparing their behavior with that of standard pyrometric cones when the cones are heated together in the same furnace.

Pyrometric cones, when used for determining the relative heat-resisting qualities of the materials for which they are applicable, give an accurate measurement of temperature only in tests which follow exactly the standard schedule of heating and other standard conditions.

The temperatures associated with the particular cones do not apply to the slower rates of heating common in commercial firing and use of refractory materials. When it is desired to interpret PCE values approximately in terms of temperature, Table 9 may be used.

Pyrometric cone equivalents for various types of refractory brick are given in Table 10. For complete details of the test, see ASTM C24-46.

Table 9. Pyrometric Cones Used in Connection with Refractories

(Based on the work of Fairchild and Peters as published in the *J. Am. Ceram. Soc.* Vol. 9, No. 11, Nov. 1926, p. 700.)

Cone No.	End Point, °F	Cone No.	End Point, °F	Cone No.	End Point, °F	Cone No.	End Point, °F
12	2435	18	2714	28	2939	33	3173

17	2687	27	2921	32 1/2 *	3131	38	3335

Note: The temperatures given are approximate.

* Not included in the tests of Fairchild and Peters.

Table 10. Pyrometric Cone Equivalents (PCE) for Various Types of Refractory Brick

Type	PCE	Temperature °F	Temperature °C
Fireclay			
Superduty	33 to 34	3173–3200	1745–1760
High-heat duty (aluminous)	31–32 to 32 1/2	3074–3137	1690–1725
High-heat duty (siliceous)	28 to 31	2939–3056	1615–1680
Intermediate-heat duty	29 to 31	2984–3056	1640–1680
Low-heat duty	19 to 26	2768–2903	1520–1595
High alumina			
50% alumina class	34 to 35	3200–3245	1760–1785
60% alumina class	35 to 36–37	3245–3299	1785–1815
70% alumina class	36 to 38	3290–3335	1810–1835
80% alumina class	38 to 39	3335–3389	1835–1865
90% alumina class	39 to 40–41	3389–3425	1865–1885

CHEMICAL REACTIONS BETWEEN REFRACTORIES. Dissimilar types of refractory brick (for example, magnesite and fireclay brick) will react chemically with each other at high temperatures. (See Table 11.) It is common practice to separate such refractories

Table 11. Reaction Temperatures between Different Refractories, °F

Type of Refractory Brick	Silica		High-heat Duty Fireclay		High Alumina (70% Al_2O_3)		Chrome		Magnesite		Forsterite	
	A	*B*	*A*	*B*	*A*	*B*	*A*	*B*	*A*	*B*	*A*	*B*
Silica	....	....	2730	*	2910	*	No reaction		2730	2910	3100	3100
High-heat duty fireclay	2730	*	....	....	No reaction		2910	*	2550	2730	2730	2910
High alumina (70% Al_2O_3)	2910	*	No reaction		.....	.....	2910	2910	2730	*	3100	3100
Chrome	No reaction		2910	*	2910	2910	.....	.....	No reaction		No reaction

Forsterite	3100	3100	2730	2910	3100	3100	No reaction		No reaction		....	

A—reaction first observed. *B*—reaction first became damaging.
* Not damaging at 3090 F.

by interposing a course of neutral material, usually chrome brick, which will not react with either.

REFRACTORINESS (see Pyrometric Cone Equivalent). The fusion point, softening point, and melting point are indefinite when applied to ceramic materials, which soften over a wide temperature range. In general, no definite temperature marks the transition from the distinctly solid to the distinctly liquid state. Instead, the pyrometric cone equivalent (PCE) is generally used as an index of the heat-resisting qualities or refractoriness of fireclay and high-alumina brick.

The ability of a refractory brick to support load at high temperatures in service is frequently of major importance. Consequently, the standard load test is of considerable significance in evaluating the refractoriness of materials for which the PCE test is not applicable.

SPALLING RESISTANCE. Spalling may be defined as the loss of fragments or spalls from the face of a refractory structure through superficial cracking and rupture, with exposure of inner portions of the original refractory mass.

Of the various types of refractory brick most widely used, superduty fireclay brick have the greatest resistance to thermal spalling. Both superduty fireclay brick and high-alumina brick may be considerably more resistant to spalling than other refractory brick in the presence of certain types of slag, owing to their high refractoriness and chemical composition which enable them to resist change in texture due to high temperature or slag action. Silica brick are extremely sensitive to temperature change below 1200 F. Magnesite and chrome brick are also sensitive to temperature change. Magnesite-chrome and chrome-magnesite brick have higher resistance to spalling than do magnesite or chrome brick.

No single method for determining resistance to spalling can be applied to all types of refractory brick. The most informative spalling test is the panel spalling test developed at the laboratory of the Refractories Fellowship of the Mellon Institute of Industrial Research, Pittsburgh, Pennsylvania. For *Basic Procedure in Panel Spalling Test*, see ASTM C38-47; see also ASTM C71-47, C107-47, C122-47, and C180-47.

Table 12. Specific Heats of Refractory Materials

	Mean Specific Heats between 32 and *t* F			
t F	Fireclay Brick	Silica Brick	Magnesite Brick	Chrome Brick
32	.193	.169	.208	.170

2200	.261	.272	.287	.222
2400	.266	.276	.293	.224
2600	.269	.279	.297	.226

SPECIFIC HEAT. The heat content of a refractory brick at any temperature is a function of its specific heat and of its weight. The rate at which it will absorb or emit heat depends upon these factors and upon its thermal conductivity and emissivity.

The figures in Table 12 appear to be the most probable values for the specific heats of refractory materials. They are based on the work of various observers, whose data do not agree with exactness.

Table 13. Weights of Refractory and Insulating Firebrick

Kind of Brick	Average Weights	
	Pounds per cubic foot	Pounds per 9-in. straight 9 × 4 1/2 × 2 1/2 in.
Chrome and chrome-magnesite	190–205	11.2–12.1
Fireclay (except superduty)	115–140	6.8– 8.2
Fireclay (superduty)	135–155	7.9– 9.1
Forsterite	150–165	8.8– 9.7
High alumina

RUBBER AND RUBBER-LIKE RESILIENT MATERIALS

By E. F. Riesing

When properly compounded, natural rubber and recently developed synthetic elastomers that are rubber-like in behavior provide the designer with engineering materials having specific properties to fill many exacting requirements. These materials will endure where no other material can qualify under the abusive action of repeated impact, continuous flexing, vibration, abrasion, and the destructive action of chemicals, oils, weather, ozone, etc.

15. ELASTOMERS AND COMPOUNDS

Various synthetic elastomers can be polymerized to produce tailor-made molecular structures. These polymer structures can be blended with other elastomers, including natural rubber, in varying percentages, making an almost infinite number of combinations of vulcanizates. All these vulcanizates can be sheeted, compression or injection molded, or extruded to practically any shape. They can be chemically or mechanically bonded or adhered to metallic or nonmetallic surfaces. They can be frictioned, skimmed, calendered, or extruded and adhered to textile or metallic fabrics or cords. They can be extended and reinforced with fillers and flocks. They can be permanently lubricated by the addition of various waxes, graphite, etc. Some elastomers can be pigmented to produce a variety of colors, including white. All elastomers have electrical insulating qualities, but some may be specially compounded to be conducting to various degrees, depending on type and quantity of carbon black filler. Further, the majority of the elastomers can also be processed into sponge structures.

From the foregoing, it is apparent that to provide technical data on all the infinite variations of structures with the different elastomers would require volumes. The data selected for presentation here therefore cover only a small practical range group that will be helpful to the design engineer for such average applications as bumpers, vibration insulators, engine and motor supports, dampers, suspension bushings, oil and grease seals, etc.

BASIC ELASTOMERS. The range group covered here includes three different Shore Durometer hardnesses (40 Durometer is a soft grade, 50 Durometer is a medium hardness, and 60 Durometer is a firm hardness) of five different basic elastomers. General properties of these, plus Thiokol, are listed in Table 1. These five basic elastomers are:

Natural rubber, a natural high polymer of isoprene coagulated from the latex of the *Hevea* tree. Natural rubber is not oil resistant, but it is the most outstanding elastomer of this entire group for elements where a minimum of energy absorption is desired and long flexing life is required.

Neoprene, a polymer of chloroprene of the monovinyl acetylene type. Neoprene compounds have the desirable characteristic of petroleum-base oil resistance in varying degrees, plus excellent resistance to acids, ozone, and flame. Neoprene compounds are used for oil-resistant hose, belting, gaskets, sheet packings, tubes, tapes, printing rollers, covering for electric wires and cables, pipe lines, etc.

Butadiene styrene, a copolymer of butadiene and styrene. Butadiene styrene copolymers have practically the same lack of resistance to oils and gasoline as natural rubber and, therefore, are definitely non-oil-resisting synthetics. Compounds of this elastomer are used extensively as a substitute for natural rubber in seals, non-oil-resisting gaskets, electric cable insulation, etc.

Butadiene acrylonitrile, a copolymer of butadiene and acrylonitrile. The butadiene acrylonitrile copolymers provide excellent resistance to petroleum-base oils or other organic fluids. Butadiene acrylonitrile compounds are widely used for oil and gasoline hose, tank linings, packings, gaskets, hydraulic piston seals, bullet sealing, gasoline tanks and hose, etc.

Butyl, a copolymer of isobutylene and small amounts of unsaturated hydrocarbons such as isoprene. Although butyl is essentially a non-oil-resistant elastomer, it does provide good resistance to some vegetable oils. However, it is most outstanding for its low rate of diffusion of gases and excellent resistance to acids and ozone. Compounds of this elastomer are recommended for application where maximum resistance to ozone and acids is required. It is extensively used for automobile-tire inner tubes because of its greater resistance to air permeability and also because of its excellent tear resistance.

PHYSICAL PROPERTIES. Table 2 gives the conventional physical properties of these elastomeric polymers and copolymers, as well as the SAE ASTM grade numbers of these five compounded elastomers in three different Shore Durometer hardnesses.

(Continued on p. 5-60)

* Compression set is the residual decrease in thickness, expressed as a percentage of the original thickness, of a test specimen measured 30 min after removal from a loading device in which it had been subjected for a definite time to compressive deformation under specified conditions of load application and temperature. (See ASTM D395-47T.)

SAE–ASTM CLASSIFICATION grade number has been used to identify each of the 15 compounds in Table 2. The key to the SAE–ASTM grade number system given in Table 3 explains prefix letters, hardness range number, tensile numbers, and suffix letters. The SAE–ASTM classification simplifies the writing of specifications for a wide range of compounds and conditions. Table 2 illustrates three elastomers in the "Type R" non-oil-resistant solid rubber classification, and two elastomers in the Type S oil-resistant solid rubber classification. For example, the designation **RN-430-ABF** indicates (Table 3) a rubber of grade 40 Durometer and 3000 psi tensile requirement, with ovenaging requirement, low compression set, and flexibility down to −40 F.

Space does not permit presenting properties of sponge rubbers referred to in the classification chart, nor has any attempt been made to tabulate properties of either the large group of rubber-like flexible plastics or the "Type SA" group of maximum oil-resistant synthetics, such as Thiokol. (Thiokol is an organic polysulfide polymer available in a variety of different types. Its general properties are given in Table 1.) Both these groups lack the resilience characteristics needed in parts under appreciable mechanical action. Some of the materials in these groups are particularly resistant to aromatic fuels; however, as a class they are subject to high permanent compression set and will not resist elevated operating temperatures.

The conventional physical property data listed in Table 2, and the SAE–ASTM classification in Table 3 may provide enough information to enable the engineer to make his selection of the proper resilient material for simple applications, working at room temperature. However, for special design work it is frequently required to know more about such

Table 3. Key to SAE-ASTM Classifications and Grade Numbers

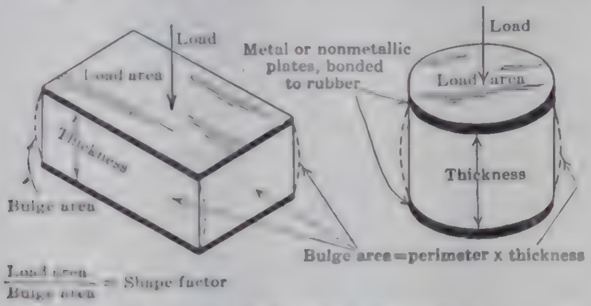
additional properties as moduli of elasticity of the compound in compression, tension, or shear; also the effect that high and low temperatures have in influencing these moduli values. It must be emphasized that the moduli values of a particular rubber manufacturer's compound that meets the SAE-ASTM conventional physical properties for a given grade and classification may, and in all probability will, vary widely from those of some other rubber manufacturer because different reinforcing materials, organic accelerators, etc., may have been used.

Therefore, in the limited space available, an attempt will be made to explain some of the properties beyond the conventional physicals, and some of the fundamentals of rubber design.

16. DESIGN OF RUBBER PARTS

COMPRESSION DESIGN. For the majority of designs for insulating impact shock, or for isolating vibration and reducing the transmission of noise, rubber-like resilient materials are utilized predominantly in compression. Most desirable results and longest life are obtained by bonding the rubber to plates, thereby preventing slippage and destructive abrasion of the load-carrying surfaces.

Designs employing rubber in compression should be calculated so as to limit the deflection under most working loads to 15 or 20% of the free unloaded height of rubber thickness; 10% is recommended. Constant high loadings causing deflections greater than 20% induce excessive permanent set and drift in the compound over long periods of time. It should also be noted that, for practical purposes, all resilient elastomers may be considered to have no volume compressibility. Actually, they are less compressible than water. To obtain resilience, therefore, the material must not be confined but must be allowed to bulge at the surfaces normal to the load-carrying area.



Load
Load area
Thickness
Bulge area=perimeter x thickness
Load area / Bulge area = Shape factor

Fig. 1. Load area and bulge area of compression mounting.

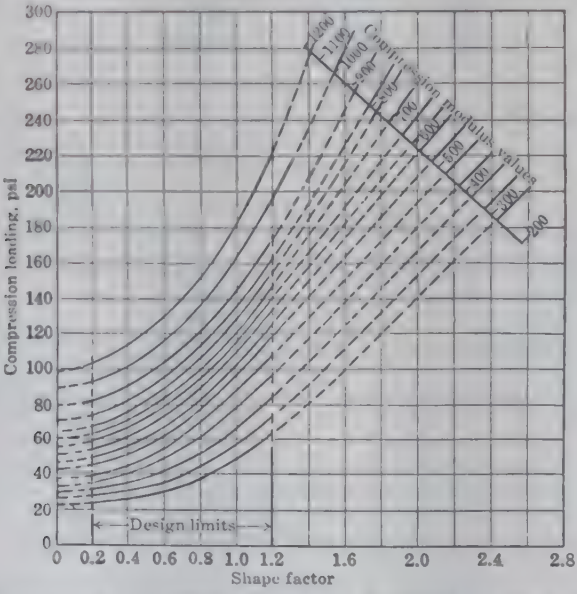

Fig. 2. Chart for determining compression modulus of elastomers for bonded compression designs of uniform thickness, for 10% deflections.

Since the compression modulus of various elastomers is so dependent on the shape of the sample tested, it is imperative that the designer keep the dimensions of the compression pad or spring under consideration to within a "shape factor" of 0.2 to 1.2. This shape factor is the ratio of *load area* to *bulge area*, Fig. 1. To facilitate calculations, Figs. 2 and 3 have been plotted for bonded compression designs for 10% and 20% deflections, respectively. These charts can be used as follows:

With the load to be supported known, the load-carrying area of the design may be determined by assuming a loading within the range of 50 to 200 psi. Thus the load to be supported, in pounds, divided by the compression loading, in pounds per square inch, equals the load area in square inches. A thickness must then be assumed. From the selected thickness and with the load area determined, the shape factor can readily be established (see Fig. 1). The intersection of the shape factor and the assumed compression loading on Fig. 2 or 3 establishes the compression modulus value of the compound required.

Compression moduli values are given in Table 4 for the 15 different compounds listed in Table 2. These values apply for deflections up to 20% compression and for static loadings as well as for dynamic loadings up to 150 cycles per minute. Compression moduli values for dynamic loadings above 150 cycles per minute should be obtained by contacting the technical division of any large rubber manufacturer. The effect of temperature on compression modulus should be noted particularly in Table 4.

Example. It is required to design a bonded compression pad to support a load of 1200 lb. Location of pad allows a thickness of 1 in., and a deflection of 20% is desired. Assuming a compression loading of 150 psi, the load area becomes 1200/150 = 8 sq in.

For a *circular disk* pad, the diameter = $\sqrt{8 \times 4/\pi}$ = 3.2 in.; hence the bulge area = $\pi \times 3.2 \times 1 = 10$ sq in. The shape factor is therefore 8/10 = 0.8, and, from Fig. 3, the elastomer must have a compression modulus of 510 psi.

For a *square* pad, the side dimension = $\sqrt{8} = 2.83$ in.; hence the bulge area = $2.83 \times 4 \times 1 = 11.3$ sq in. The shape factor is therefore 8/11.3 = 0.71, and, from Fig. 3, the elastomer must have a compression modulus of 550 psi.

For a *rectangular* pad where the length of the pad is twice the width, the dimensions should be $2 \times 8 = 8$; hence the bulge area = $2 \times (2 + 4) \times 1 = 12$ sq in. The shape factor is 0.667, and, from Fig. 3, the elastomer should have a compression modulus of 590 psi.

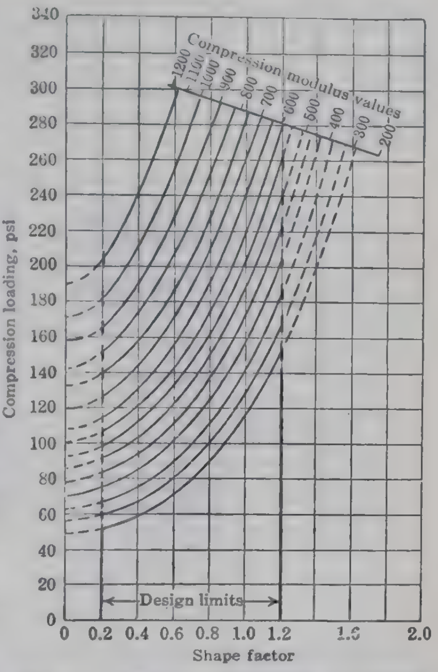

Fig. 3. Chart for determining compression modulus of elastomers for bonded compression designs of uniform thickness, for 20% deflections.

It should be noted that, as the perimeter of the pad keeps increasing, providing a larger bulge area, the necessary modulus increases if the same deflection is to be maintained.

Table 4. Compression Modulus, psi

(Up to 20% compression)

Temperature	Natural Rubber	Neoprene	Butadiene Styrene	Butadiene Acrylonitrile	Butyl
		40 Durometer			
158 F	400	470	360	212	340
70 F	405	475	415	270	360
0 F	410	480	810	2100	420
		50 Durometer			
158 F	540	690	480	340	410
70 F	635	700	620	500	460
0 F	690	900	880	3250	660
		60 Durometer			
158 F	990	900	660	460	540
70 F	1050	915	800	685	620
0 F	1250	940	1350	4300	900

The charts may be employed in reverse process also; that is, with the compression modulus known for a definite compound, the desirable compression loading in pounds per square inch can be established. Interpolations can also be made on the charts. Results should be accurate within 10 to 15%.

The outstanding feature of Figs. 2 and 3 is that the compression modulus values obtained will apply for any of the natural rubber and synthetic rubber compounds listed in the SAE ASTM classifications of RN, RS, SC, and SB. The compression modulus value obtained by the foregoing method, along with information as to the type of service to which the compression pad or spring will be placed, the service temperature, whether oil or non-oil conditions exist, whether the design is subject to impact or occasional overloads, etc., will make it possible to procure the properly compounded elastomer.

The data in Figs. 2 and 3 resulted from a study of a large number of rubber compression pads and springs vulcanized of a variety of compounds of different elastomers, in various sizes, thicknesses, and shapes such as square, rectangular, and cubical, and in solid and hollow cylindrical forms bonded to plates. Tests have proved that similar compression elements bonded to metal plates, made of the identical compound and vulcanized to the same degree of cure, will have the same stress-strain curves up to 20% strain.

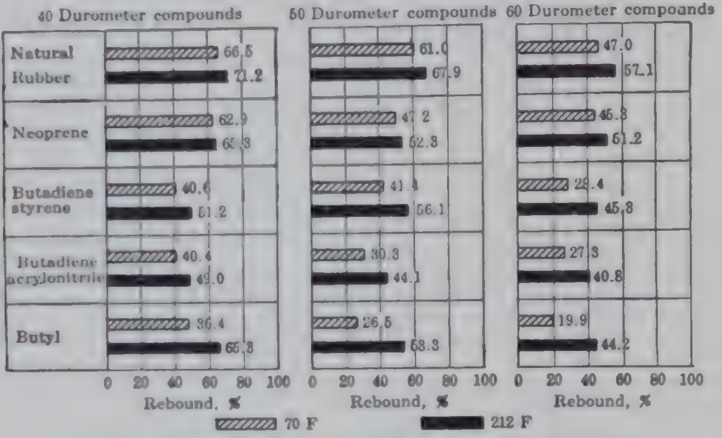

FIG. 4. Impact resilience of rubber and synthetic compounds.

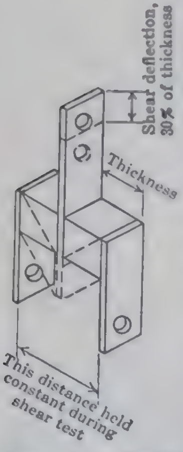
Impact Resilience. Bumper designs or compression pads subject to periodic impact warrant the investigation by the designer of the impact resilience values. Resilience can be determined by several methods. The ball rebound device is an excellent, easy way to draw comparisons between various compounded elastomers and can be employed as an inexpensive production method of inspection on some shapes of the finished molded or extruded vulcanizate. Simple energy considerations based on the theory of free vibration show that the ball rebound device permits calculation of a factor which can be called impact resilience. This value is expressed by dividing the first rebound height H_1 by the distance of the free fall H_0.

$$\frac{H_1}{H_0} \times 100 = \text{Impact resilience, }\%$$

Figure 4 shows, in bar graph form, the impact resilience values at 70 F room temperature and the change in these values caused by the elevation in temperature to 212 F for the same 15 compounds listed in Table 2.

The hysteresis or internal friction of a compounded elastomer is an important factor when considering load-carrying insulators that are subject to vibrations of variable impressed frequencies that may force the resilient load-carrying insulator through a short-interval resonance period. Hysteresis is a function of the energy absorbed by the resilient compounded elastomer when forces are applied to it. It may be measured by the area of the "hysteresis loop" of the stress-strain extension-retraction diagram, or by the decay of free vibrations. The hysteresis value varies with temperature and frequency.



Shear deflection, 30% of thickness
Thickness
This distance held constant during shear test

FIG. 5. Simple shear design consisting of a pair of single shear rubber sandwiches.

SHEAR DESIGNS. Designs requiring large deflections and low natural frequency oscillations cannot be satisfied by stressing the elastomers in compression. Designs of this type should utilize the resilient material by stressing it in simple shear when bonded to metal plates. Rubber is most compliant when used in simple shear, since the modulus of elasticity in shear is approximately one-sixth the compression modulus when bonded to plates. Theoretically the shear modulus should be one-third compression modulus for small deformations. This is based on studies with glycerin-lubricated compression surfaces on which the coefficient of friction is reduced to almost zero. However, experimental data obtained under conditions of 20% compression deflection between bonded plates have shown that this ratio is close to 1/6.

The basic simple form for this design is a pair of single shear sandwiches, such as pictured in Fig. 5. If greater deflections are necessary than can be obtained by a pair of single shear sandwiches, the designer may resort to a double pair or a quadruple pair. For a pair of single shear sandwiches, the following formula applies:

$$d = \frac{WT}{AG_s}$$

Also

$$\text{Shear rate per inch} = \frac{W}{d} = \frac{AG_s}{T}$$

where d = shear deflection, inches; W = load, pounds; T = free molded thickness, inches (not laterally compressed thickness); A = twice the area, square inches, at smallest cross section; and G_s = shear modulus, pounds per square inch (see Table 5).

Note: Correction must be made in the shear modulus value where the ratio d/T is more than 0.3. The value of G_s must be multiplied by 0.9 where d/T is 0.35 to 0.8; and it must be multiplied by 0.833 if the value of d/T is 0.8 to 1.2.

Table 5. Shear Modulus at 30% Deflection

(See Fig. 5)

70 F	134	127	126	110	90
0 F	147	153	183	257	93

Where square, rectangular, or circular shear sandwich constructions are used, the static shear stress limit should be 20 to 30 psi of the smallest bonded area. This applies to engine mountings, motor supports, resilient wheels, and rubber springs of various types where permanent set in the rubber is an important consideration. In designs of this type, stress relief at the edges of the rubber should always be worked into the design by the incorporation of fillets in the rubber or radii on the edge of the metal part or both, inasmuch as most fatigue failures start at the edge of the bond. It should be noted here that lateral compression of the rubber in the shear sandwich is frequently resorted to by the designer in order to facilitate anchoring of the metal elements to which the rubber in shear is bonded. This lateral compression changes the shear characteristics of the design only slightly, for lateral compression loadings ranging from 10 to 50 psi, with shear calculations based on the original free thickness between the bonded plates. Table 5 gives moduli of elasticity values in shear for 30% deflection when load is applied parallel to the bonded surfaces, for the 15 compounds referred to in Table 2. Here, again, the effect of temperature is shown in influencing the shear rate or modulus.

The effect of high and low temperatures on the stiffness or modulus of natural and synthetic rubbers cannot be minimized. This must be fully recognized by the design engineer for resilient applications operating at temperatures above and below room temperatures. At temperatures of 0 F and lower, some of the elastomers rapidly begin to lose their elasticity, some actually crystallize, and others harden to a point where the material is not serviceable. At temperatures of 158 F and above, aging effects take place rapidly and shorten the service life. Both the tension modulus and the Young's modulus values illustrate outstandingly this temperature influence. Table 6 shows the change of ultimate tensile strength and the change in elongation at rupture for temperatures of 70, 158, and 212 F for the 15 compounds.

The reaction of these elastomers to temperatures above and below room temperatures as indicated in the tabulation is not to be confused with the "Joule effect." The Joule effect phenomenon occurs while the elastomer is under strain; an increase in temperature tends to contract or tighten up the molecular structure, and lowering the temperature causes an opposite condition of relaxing the structure.

Table 6. Effect of Temperature Change on Tensile Strength and Elongation at Rupture

The effect of low temperature on the 15 compounds in Table 2 can best be illustrated by showing the stiffening effect on the Young's modulus of elasticity, see Figs. 6, 7, and 8. Young's modulus is calculated by means of the beam bending formula:

$$E = \frac{Wl^3}{4dbh^3}$$

where E = Young's modulus, pounds per square inch; W = load producing a deflection, pounds; d = deflection produced by load W, inches; l = distance between center lines of

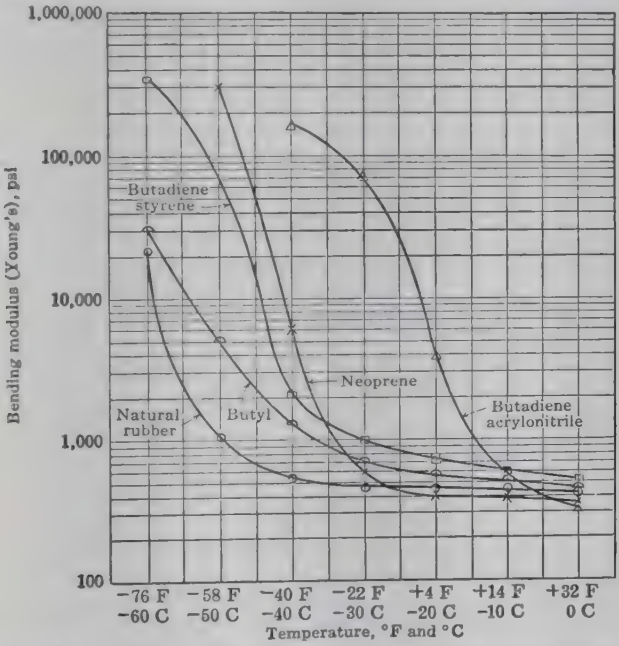

FIG. 6. Effect of temperature on elastic modulus for compounds of 40 durometer hardness.

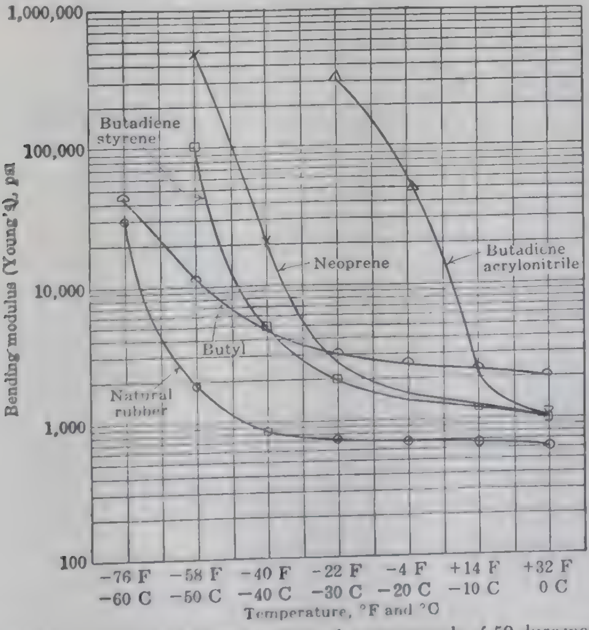

FIG. 7. Effect of temperature on elastic modulus for compounds of 50 durometer hardness

sample supports, inches; b = width of sample, inches; and h = thickness of sample, inches.

A cylindrical rubber spring for loading parallel to the longitudinal centerline is illustrated in Fig. 9. Deflection of this type of spring may be calculated from the following formula:

$$d = \frac{W}{2\pi G_s}\left(\frac{r_2 - r_1}{h_2 r_1 - h_1 r_2}\right)(\log_e h_2 r_1 - \log_e h_1 r_2)$$

where d = deflection, inches; W = load, pounds; h_1 = height of bonded area on inside tube, inches; h_2 = height of bonded area on outside tube, inches; r_1 = radius of bonded area on inside tube, inches; r_2 = radius of bonded area on outside tube, inches; and G_s = modulus of elasticity of rubber in shear, pounds per square inch.

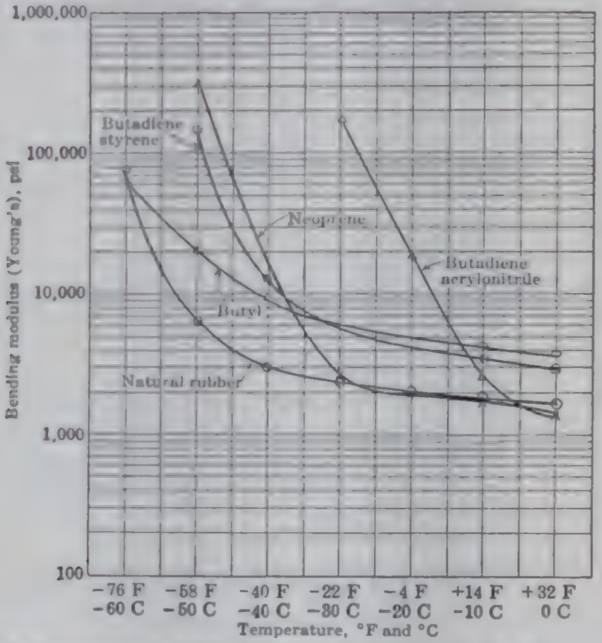

FIG. 8. Effect of temperature on elastic modulus for compounds of 60 durometer hardness.

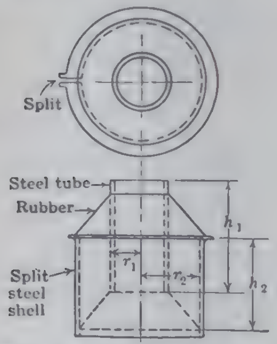

FIG. 9. Cylindrical rubber spring for loading parallel to longitudinal center line.

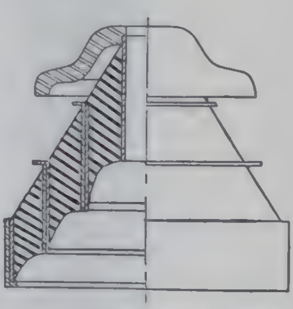

FIG. 10. Three-stage cylindrical rubber spring.

A three-stage cylindrical rubber spring is shown in Fig. 10. Deflection of the separate stages may be calculated by the foregoing formula, the total deflection being the sum of the separate deflections.

TORSION RUBBER BONDED TYPE BUSHING. In this design, Fig. 11, rubber is bonded to inner and outer tubular concentric metals. The ends of the rubber in these designs should be contoured to relieve concentration of stress at the smallest bonded area, the length of the rubber being greater on the small tube than on the outer. The rubber should preferably be under radial compression in the final assembly, even if only to 3% radial compression.

The following formula can be used for design of rubber torsion bushings or springs for ratios of thickness of rubber to shaft diameter of 0.3 to 0.7 (see Fig. 11):

$$\theta = \frac{Wl}{4\pi B G_s}\left(\frac{1}{r_1^2} - \frac{1}{r_2^2}\right)$$

where Wl = torque, inch-pounds; θ = angular deflection, radians; B = effective length of rubber, inches; r_1 = radius of inside bonded area of rubber, inches; r_2 = radius of outside bonded area of rubber, inches; and G_s = modulus of elasticity in shear, pounds per square inch.

Two factors that must be considered in the design of rubber torsion springs are the stress on the bonded area and the strain in the rubber. Referring to Fig. 11, for a given angular movement θ of the torsion bushing, the strand of rubber ab becomes approximately ac, and the ratio of stretch to initial length is $(ac - ab)/ab$. The length ac, from the geometry of the figure, is equal to

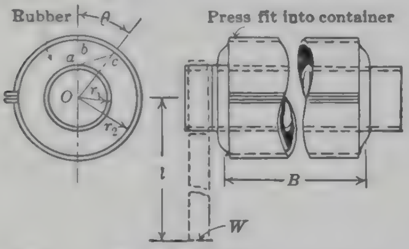

FIG. 11. Bonded rubber torsion spring.

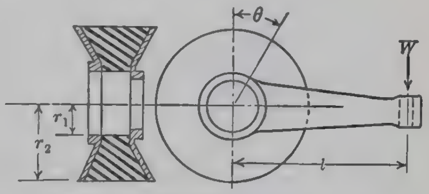

FIG. 12. Modified torsion spring.

$$ac = \sqrt{r_1^2 + r_2^2 - 2r_1r_2\cos\theta}$$

If ab is small in proportion to r_1, the strain in the rubber for an angular movement θ will be excessive, even though the stress on the bonded area of the inner metal shell is low. Conversely, if ab is large in proportion to r_1, the strain in the rubber will be low, even though the stress on the bonded area is high. Hence, in the design of these bushings, it is best to limit the strain in the rubber to approximately 80% and the bond to approximately 110 psi of the area of the inner shaft under normal static loading.

A modified torsion spring is illustrated in Fig. 12. The formula for angular deflection of this type is

$$\theta = \frac{2WlT}{G_s(r_2^4 - r_1^4)}$$

where θ = angular deflection, radians; Wl = torque, inch-pounds; T = mean thickness of rubber, inches; r_1 = inside radius of rubber, inches; r_2 = outside radius of rubber, inches; and G_s = modulus of elasticity of rubber in shear, pounds per square inch.

SILICONES

By Arthur M. Weinberg

The silicones are a group of versatile synthetics developed through research in the field of organo-silicon chemistry. They are semiorganics combining the most desirable virtues of organic and inorganic substances. They possess, to a high degree, immunity to heat, cold, chemicals, and weathering.

Silicone products now being produced are classed as *water repellents*, *resins*, *oils and greases*, and *rubber*. These compounds differ chemically only in the number and arrangement of the organic groups attached to the —Si—O—Si— backbone.

WATER REPELLENTS. The water repellents are a group of liquids which enable surfaces of materials such as ceramics, paper, fabrics, plastics, glass, quartz, and leather to shed water. On many surfaces they produce a far higher degree of water repellency than can be obtained with any other materials. A typical repellent has the following advantages in comparison to wax coatings for treating steatite and porcelain insulators: (1) freedom from plugging small holes; (2) resistance to solvents, permitting cleaning after assembly operations; (3) cleaning of soldering fluxes possible without damaging coating; (4) superior electrical properties under long humidity cycles.

RESINS. Silicone resins resemble closely conventional resins in appearance but combine high thermal stability at machinery operating temperatures, improved dielectric properties, and improved resistance to moisture and severe chemical conditions. Their greater thermal stability makes possible a reduction in size and weight of equipment without a corresponding reduction in service rating; an increased motor output where operating temperatures can be raised; longer life at normal operating temperatures; and a much greater safety factor where severe overloads sometimes occur.

Silicone resins are baked at slightly higher temperatures than ordinary resins and are furnished with ordinary commercial solvents. They are particularly valuable as coatings, impregnants, and bonding agents where extremely high (482 F) or low (−58 F) temperatures are encountered. Table 1 shows characteristics of a typical silicone resin, and Table 2 shows chemical resistance of three silicone resins.

Table 1. Typical Silicone Resin

(Data from General Electric Co.)

Base, %	58–60
Color	Light straw
Drying time, 3-mil film on aluminum panel	
Room temperature	10 min
212 F	5 min
302 F	5 min
392 F	5 min
Rocker hardness (bake 2 hr, 302 F)	34
Gloss	Very good
Craze life, 482 F, glass tape	720 hr
Flexibility, 482 F, 3-mil film, iron plate, 1/8-in. mandrel	96 days
Recommended cure * (thin films)	
347 F	24 hr
392 F	8–10 hr
482 F	2–4 hr
Tensile strength, room temperature, cure 48 hr at 482 F	1800 psi

* A precure of 1/2 1 hr at 257–302 F to eliminate bubbling is recommended.

CCl_4	Softens and swells	Softens	Softens and swells
Oil (25 C) (No. 10 transil)	Softens	Softens slightly	Unattacked
Oil (100 C) (No. 10 transil)	Softens	Softens slightly	Softens slightly

Silicone resin-based protective and decorative finishes are unusually weather resistant, durable under high temperatures, and generally impervious to chemicals. Pigments are dispersed in silicone resins with ball or roller mills. Metal salts such as cobalt, iron, and zinc are added to catalyze curing, and common aromatic and aliphatic solvents thin them for more convenient application. Coatings are applied by spraying, rolling, dipping, or knifing, and are baked or cured at 400 F from 30 to 60 min. A single silicone paint may resist both high and low temperatures (−60 F to +500 F), withstand exposure to both acids and alkalies, and be both hard and flexible.

OILS AND GREASES. Silicone oils are clear, water-white liquids made in viscosities ranging from light machine oils to oils of semisolid consistencies. They possess three outstanding properties: low flow point (−121 F to +130 F); high-temperature stability depending on conditions (300 to 500 F); minimum change in viscosity from low to high temperatures. (See Fig. 1, p. 12-62.) These properties make silicone oils of interest as hydraulic fluids for aircraft, machine tools, fluid couplings, hydraulic brakes, and clutches, as manometer fluids, as cooling or heating baths, and, with some limitations, as lubricants. High solid emulsions of silicone oil (85%) are available for mold release applications and are particularly suitable for use in the rubber industry for tires, heels and soles, and mechanical rubber goods.

The silicone oils are inert in contact with common metals and plastics up to 300 F and have excellent electrical properties which recommend them as dielectric fluids for transformers and capacitors. (See Table 3.) These oils are available in viscosities ranging from 4 to 1000 centistokes at 100 F. (See Fig. 1, p. 12-62.) Intermediate viscosities between the standards are obtained by blending the oils. Oxidation inhibitors can be added to the oil to extend its temperature range and life.

Table 3. Some Properties of Silicone Oils

(Data from General Electric Co.)

Surface tension, dynes/cm	20
Solubility of air in oil at 82 F, by volume, %	21
Specific heat at 80 F, Btu/lb	0.47

The silicone oils are remarkably stable to heat and oxidation and remain free from discoloration, acid formation, sludging, and similar phenomena in the presence of air at temperatures as high as 300 F. Copper, bronze, brass, aluminum, magnesium, steel, tin, cadmium, and chromium are not affected by the oil. Silicone oils are miscible in petroleum ether, naphthas, ether, benzene, toluene, xylene, chloroform, carbon tetrachloride, amyl alcohol, and ethyl acetate; partially miscible with methanol, ethanol, propanol, butanol, and acetone; and immiscible with water and petroleum oils. Silicone oils have been added to paints and petroleum oil in extremely small quantities to prevent foaming. They have also been useful in preventing floating, streaking, and flocculation in paints and enamels.

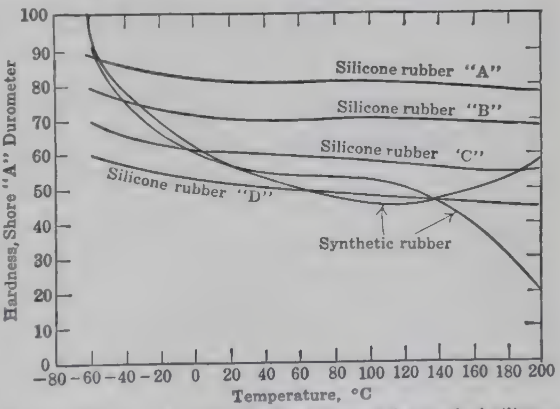

Fig. 1. Hardness vs. temperature change for typical silicone rubbers, compared with synthetic rubbers.

Silicone greases with semilubricating qualities have been developed for lubricating plug cocks and valves. The greases are stable over temperatures ranging from −70 to +400 F.

SILICONE RUBBER. Silicone rubber can be held continuously at temperatures of 300 to 350 F with little increase in surface hardness or decrease in flexibility and resilience. (See Fig. 1.) It does not soften and become sticky at 520 F and can be held at this temperature for hours (Table 4). With standard compression set procedure D395-37T, General Electric silicone rubber showed compression set values of 8 to 10%, which compares favorably with natural rubber stocks. Silicone rubber remains flexible and resilient down to −70 F, and no plasticizer is needed to improve low-temperature characteristics.

Polymeric silicone gum may be compounded with some fillers used in the rubber industry and can be processed on standard rubber equipment. It may be extruded in a standard continuous extrusion machine and molded and vulcanized in a steam-heated press. Vulcanization with sulfur is not possible, but other methods have been developed.

Silicone rubber may be made to any desired hardness over the range 40 to 85 as measured with a Shore "A" Durometer. The harder rubbers have slightly less tear resistance and a higher modulus with a relatively small elongation. The tensile strength of silicone rubber

Table 4. Typical Mechanical Properties of Silicone Rubbers Before and After Exposure to High Temperature

(Data from General Electric Co.)

	Rubber A	Rubber B	Rubber C	Rubber D
Original properties				
Hardness (Shore "A" Durometer)	75–85	65–75	55–65	45–55
Tensile strength, psi	500	650	450	200

Hardness change	+6–8	+8–10	+15–20	+15–20
Tensile change, %	±0	±0	+5	+20
Elongation change, %	−25	−25	−50	−50
Weight loss, %	2–3	2–3	2–3	2–3
Low-temperature resistance, flex test after 6 hr				
At −60 C	No cracks or crazing	No cracks or crazing	No cracks or crazing	No cracks or crazing
At −76 F				
Compression set				
Compression 30%, 22 hr at 70 C (158 F)	10%	10%	15%	10%
Compression 30%, 6 hr at 150 C (302 F)	25%	25%	40%	30%

is lower than that of most natural rubbers except at high temperatures, and the most probable value of tensile strength for a break is from 500 to 600 psi. Maximum elongation varies between 100 and 300%. Tear resistance of silicone rubber as compared to conventional rubbers is relatively poor, although inorganic fabrics can be added to improve tear resistance.

Silicone rubber in contact with metals has no corrosion action because of its chemical inertness and because it contains no added ingredients which might cause such corrosion. Special techniques have been developed for bonding silicone rubber to metals, and a special adhesive developed by the General Electric Co. will also bond silicone rubber to itself.

Table 5 gives data on the relative chemical resistances of four typical silicone rubbers.

WOOD

By L. J. Markwardt

17. PROPERTIES OF WOOD *

(Data from U. S. Forest Products Laboratory, Madison, Wis.)

CHEMICAL COMPOSITION. Although proportions of the elements comprising wood vary with species, with heartwood and sapwood, and among individual pieces of a species, the different woods nevertheless exhibit generally similar chemical characteristics. Average results of analyses of the sapwood and heartwood of larch, pine, spruce, oak, and beech are as follows: carbon, 50%; oxygen, 43 $^1/_2$%; hydrogen, 6%; nitrogen, $^1/_4$%; and ash $^1/_4$% (*F.P.L. Technical Note* 235, U. S. Department of Agriculture).

From the standpoint of basic components of primary importance in chemical conversion and utilization, the composition of wood is as follows: inorganic material, $^1/_2$%; extractives, 5 $^1/_2$%; lignin, 22%; and holocellulose, 72%, the holocellulose being separable into hemicellulose (23%) and alpha cellulose (49%). Lignin forms the major portion of the complex material which serves to bind the cellulose fibers together; it is also distributed throughout the fiber wall.

It is impossible by chemical analysis to identify wood as to species. Physical structure provides the most satisfactory basis for identifying wood samples, and keys for identification by this means are available (*U. S. Dept. Agr. Misc. Cir.* 66; U.S.D.A. Forest Service, *Guidebook for the Identification of Woods Used for Ties and Timbers*).

Broad-leaved species (so-called hardwoods) differ from coniferous woods (so-called softwoods) in that they are about twice as high in pentosan content, give a higher yield of acetic acid on hydrolysis, and are usually higher in methoxyl content.

FUEL VALUE. The calorific value of dry wood is closely related to its density and is influenced further by the resin content. For information on the composition and heating value of wood see the *Power* Volume, Kent's *Mechanical Engineers' Handbook*, p. 2-40.

CHARACTERISTICS AND USES. Commercial woods are listed in the following pages, with notes on their characteristics and chief uses. (See also Table 2, p. 5-84.)

Alder, red (*Alnus rubra*) grows along the Pacific coast from Washington to California. Although red alder is mainly of local importance, it is the leading hardwood of the Pacific Northwest. The color varies from almost white to pale pinkish brown. The pores are comparatively small, fairly uniform in size, and uniformly distributed. The wood is moderately light (28 lb per cu ft, air dry), rather weak, low in shock resistance, moderately stiff, and shrinks little. It is used chiefly for furniture.

Ash (*Fraxinus* species) comprises some 18 species native to the United States. Commercial white ash, composed principally of white and green ash, is grown in the eastern United States. Commercial white ash ranks high in weight (41 lb per cu ft, air dry), strength, hardness, shock resistance, resistance to wear, and ability to retain shape. This combination of properties makes the wood especially desirable for such uses as handles, vehicle parts, and agricultural implements. In selecting ash, material from the swelled butts of swamp-grown trees, which is frequently low in weight, shock resistance, and stiffness, should be avoided.

Aspen (*Populus tremuloides*) grows in northern United States, east of the Rocky Mountains. It is one of the most widely distributed trees in the United States. The wood is soft, weak, moderately light in weight (26 lb per cu ft, air dry), uniform in texture, and easily worked; it seasons rapidly, although it is subject to warping and checking, and decays rapidly under damp conditions. The broad sapwood is creamy white, and the heartwood is light brown. The principal market for aspen logs is for pulp, although the species is also used for lumber, shipping containers, cooperage, excelsior, and matches.

Basswood (*Tilia glabra*) is distributed over the eastern half of the United States, the greater portion coming from the Great Lakes region. Basswood is light in weight (26 lb per cu ft, air dry), low in strength, soft in texture, easily workable, and straight grained. The heartwood is creamy brown, and the sapwood creamy white, changing more or less gradually into the heartwood. The sapwood, especially when of rapid growth, has a clean look that, with its other qualities, makes it particularly desirable for boxes, fruit baskets, and woodenware. Other important uses are for furniture and millwork.

Beech (*Fagus grandifolia*) grows throughout the eastern part of the United States. The wood of beech is heavy (45 lb per cu ft, air dry), strong, hard, of uniform texture, does not impart taste or odor to food, and resists abrasion. It is low in resistance to decay. Beech is used for flooring, chairs, and other furniture, handles, woodenware, and laundry appliances. It is also highly suitable for food containers and when treated is used for railway ties.

---

* See also O. W. Eshbach, Editor, *Handbook of Engineering Fundamentals*, John Wiley and Sons, New York, 1936, p. 12-38.

Birch. Between 15 and 20 species of birch grow in the United States. Of these, yellow birch (*Betula lutea*) is by far the most abundant and most important commercially. Sweet birch (*B. lenta*) ranks next, followed by paper birch (*B. papyrifera*). Yellow birch, sweet birch, and paper birch grow principally in the northeastern part of the United States, in the Lake States, and in the Appalachian Mountains. Yellow and sweet birch are cut and sold without distinction simply as birch. Yellow birch has white sapwood and light reddish-brown heartwood. Sweet birch has light-brown sapwood and dark-brown heartwood tinged with red. The wood of both yellow birch and sweet birch is heavy (average 44 lb per cu ft, air dry), hard, stiff, and strong, and has good shock-resisting ability. It is low in natural resistance to decay. The wood is fine and uniform in texture and is capable of taking a beautiful natural finish. Interior finish and furniture take a large part of the birch cut. Other uses are flooring, musical instruments, treated railway ties, and woodenware.

Cedar, Alaska yellow, (*Chamaecyparis nootkatensis*) grows in the Pacific coast region of North America from southwestern Alaska to northern Oregon. The wood is of a fine, uniform texture and has very small shrinkage. It is moderately light (31 lb per cu ft, air dry) and moderately low in strength. It has excellent working and finishing properties and ranks high in resistance to decay. The heartwood is a bright, clear yellow, and the thin, scarcely distinguishable sapwood is a shade lighter. A large part of the cut is used locally for interior finish, furniture, small boat hulls, cabinet work, and novelties.

Cedar, Port Orford white, (*Chamaecyparis lawsoniana*) grows naturally only in a narrow belt bordering the coast of southern Oregon and northern California. The heartwood, which is highly resistant to decay, is light yellow to pale brown in color, and the usually thin sapwood is of similar appearance. The wood is moderately light in weight (29 lb per cu ft, air dry), of moderate strength and hardness, with a fine and unusually uniform texture and a spicy odor. It is used for battery separators, Venetian blinds, boats, interior finish, siding, and shingles. The lower grades are consumed in dock plank, ties, mine timbers, and general construction purposes.

Cedar, western red, (*Thuja plicata*) is an important tree in the humid regions along the North Pacific coast and extends inland from Washington to Montana. The heartwood is reddish brown, and the narrow sapwood is white. The wood is light in weight (23 lb per cu ft, air dry), easily worked, rather soft and weak and has very little shrinkage. The heartwood is highly resistant to decay. Western red cedar is used for shingles, siding, porch columns, and greenhouse construction, where durability and ease of working are important factors. It holds paint well. Large quantities are used for poles and posts. It is not used extensively for piling, since the wood is likely to crush under heavy driving.

Cedar, white, includes two species, northern white (*Thuja occidentalis*) and southern white cedar (*Chamaecyparis thyoides*). Northern white cedar grows in the Lake States and in the northeastern part of the United States. Southern white cedar grows in the eastern part of the United States, near the coast. Both woods are very light in weight (22 and 23 lb per cu ft, air dry, respectively), of low shrinkage, and soft, brittle, and weak. They split readily and have a characteristic aromatic odor. Their texture is fine and uniform. The heartwood, which is resistant to decay, is light brown with a reddish tinge. The sapwood is lighter in color than the heartwood, sometimes nearly white. Northern white cedar, which is a relatively small tree, is used principally for posts, ties, poles, and shingles. It is especially desirable for service in contact with the ground. The small quantity of lumber that is manufactured is used principally in small-boat construction. Southern white cedar, which is a medium-sized tree, is used for shingles, lumber, woodenware, posts, and poles. The lumber, which contains many knots, is made into siding, porch lumber, tanks, and boxes.

Cherry, black, (*Prunus serotina*) grows from Maine to eastern North Dakota and southward to central Florida and central Texas. It is, however, scattered sparsely throughout the forests. The scattered distribution over a large area insures a fairly steady though limited supply. The wood of black cherry is strong and moderately hard; it has good shock-resisting ability, a moderate degree of stiffness, and a very moderate shrinkage. Density is 35 lb per cu ft, air dry. The heartwood varies in color from light to dark reddish brown and has a beautiful and distinctive luster. The sapwood is narrow and nearly white. The annual rings show on a cross section but are not prominent. The wood has a fairly uniform texture and contains numerous scattered pores. Black cherry stays in place well after seasoning. It is exceptionally well suited for engraver's block and is also desirable for paneling and furniture.

Chestnut (*Castanea dentata*), which has long been one of our important commercial woods, has many uses. The blight that is now exterminating chestnut is only the bark disease, so that virtually all the wood of blight-killed chestnut trees is entirely satisfactory for lumber if the trees are cut and utilized before checking, insect attack, or decay begins. The principal commercial range of this species was in southern New England and the Appalachian Mountains. Most of the remaining chestnut timber is in the southern Appalachians. Chestnut is moderately low in weight (30 lb per cu ft, air dry) and strength, is straight grained, and stays in place well. The wood has large distinct pores, and the sapwood is narrow. The heartwood, which is grayish brown, is highly resistant to decay. Poles and fence posts are among the important uses for chestnut. Planing-mill products, core stock in veneer panels, caskets and coffins, furniture, and boxes and crates are other extensive uses.

Cottonwood includes 10 or 12 closely related species of trees that grow in the United States, of which eastern cottonwood (*Populus deltoides*) and northern black cottonwood (*P. trichocarpa hastata*) are the most important. Eastern cottonwood is widely distributed east of the Rocky Mountains, and black cottonwood in the Northwest. The wood is light in weight (28 and 24 lb per cu ft, air dry, respectively), weak, and has a tendency to warp in seasoning. It is odorless, has unusually uniform texture, works nicely, and does not split easily. The annual growth rings are scarcely noticeable. It decays quickly when in contact with the ground.

Uses include boxes and crates, vehicle parts, planing-mill products, agricultural implements, woodenware, laundry appliances, and trunks. In addition to the lumber cut, large amounts of cottonwood are cut into veneer.

Cypress, bald, (*Taxodium distichum*) is found in the low swamp lands along the southeastern coast of the United States and as far up the Mississippi River Valley as Missouri. When grown in swamps near salt water, lumber from this species is called, by the trade, red cypress or tidewater red cypress, and the inland or upland growth is called yellow or white cypress. The heartwood from cypress near salt water will vary in color from slightly reddish to almost black, whereas that found farther inland is only slightly reddish or yellowish brown. Bald cypress is moderately light (32 lb per cu ft, air dry) and moderately strong, and the heartwood is highly resistant to decay. The wood is largely used where such resistance is an important factor. It holds paint well. Doors, sash, porch material, siding, tanks, and greenhouse construction are among the important uses for southern cypress.

Douglas fir (*Pseudotsuga taxifolia*) grows from the Rocky Mountain region to the Pacific Northwest. The strongest wood of this species, as well as the greatest volume of production, comes from the coastal region of Washington, Oregon, and California. Some Douglas fir trees in the coast region are very large—up to 8 ft in diameter, breast high. On rare occasions, trees up to 14 ft are found. The quality of the wood in different portions of these trees varies greatly. Douglas fir in the form of lumber and timbers is one of the most desirable native woods for structural purposes and also is extensively used for poles, piling, and ties. Large quantities are cut into veneer for plywood and other purposes. It is strong, moderately hard and heavy (34 lb per cu ft, air dry), and the heartwood is moderately durable. In general, it has a tendency to check and split and does not hold paint well, although its paint retention can be materially improved. All virgin Douglas fir has little sapwood. The existing stand of merchantable Douglas fir is larger than that of any other species.

Elm. The three species constituting the greater part of the elm lumber produced in the United States are American (*Ulmus americana*), slippery (*U. fulva*), and rock elm (*U. racemosa*). The growth range of American and slippery elm (sold as commercial soft elm) includes most of the area east of the Rocky Mountains. Rock elm is confined largely to the North Central States. The principal supply of these three species comes from the Lake States and the Mississippi Valley. Rock elm is heavy (44 lb per cu ft, air dry), hard, and strong, and has a high capacity to resist shock. It is valuable for its strength and bending qualities. Soft elm is lighter (35 to 37 lb per cu ft) and has lower strength properties than rock elm, although very dense pieces have sufficient strength to be used with rock elm. Elm, in general, is used to a large extent for slack cooperage, some vehicle parts, and boxes and crates.

Fir, balsam, (*Abies balsamea*) grows principally in New England, southward to Pennsylvania, and in the Lake States. The wood is nearly white and has little figure. It is light in weight (25 lb per cu ft, air dry), soft, and low in strength. Much of it is used in rough form for buildings.

Fir, white, (*Abies concolor*) and **lowland white fir** (*A. grandis*) are both known commercially as white fir. Lowland white fir is cut mainly in Idaho and in California near the coast, and true white fir in the mountain region of California. Commercial white fir is light in weight (27 lb per cu ft, air dry) and moderately low in strength, moderately soft, straight grained, of medium and fairly uniform texture, nonresinous, and easily worked. Its resistance to decay is low. The heartwood is white with a reddish tinge, and the sapwood is not distinguishable from the heartwood. It has less color than any other commercial softwood. The chief consumption of this wood is in the construction of small houses, largely as dimension and common boards. Other uses are for general millwork, planing-mill products, and boxes.

Gum, sweet, (*Liquidambar styraciflua*) is a native of the swamp and bottom lands in the South that are dry for the greater part of the year. Although its tendency to warp badly in seasoning long kept it out of commercial use, research ultimately found the proper methods of drying and handling. Consequently, sweet gum lumber, as produced by responsible manufacturers, has for years been a satisfactory commercial material. The color of the heartwood, which is sold as red gum, ranges from a light to a deep reddish brown. The sapwood, which is commercially called sap gum and looked upon as a distinct kind of lumber, is nearly white. The wood is moderately heavy (34 lb per cu ft, air dry) and strong, of fine, uniform texture, and will take a beautiful finish. The heartwood is moderately durable. Sweet gum is used both in lumber and veneered form for finish and furniture. The lower grades are used for boxes and crates.

Hackberry (*Celtis occidentalis*) grows from New England to Virginia and westward to eastern North Dakota, Iowa, southwestern Missouri, and western Kansas. Sugarberry (*C. laevigata*) occurs from the coast of Virginia to southern Florida, and westward through the Gulf States to the valley of the Rio Grande and to eastern Texas, Arkansas, eastern Oklahoma, Missouri, eastern Kansas, southern Illinois, Indiana, Kentucky, and Tennessee. Both sugarberry and hackberry species are marketed as hackberry, though hackberry represents the far greater percentage of the lumber cut. Both species occur in stands associated with elm, walnut, hickory, ash, and other hardwood species. Although hackberry is widely distributed, its commercial range is chiefly the river bottoms and creek valleys of the Middle West. The annual reported cut is not large, but this is only a part of the total output, since it is often sold with the lower grades and for the less exacting uses of ash and also sometimes sold with elm. In color it is more yellowish than ash, but in its annual rings of growth it resembles that wood. The wood is moderately heavy (37 lb per cu ft, air dry), rather weak as a beam, is limber, good in shock resistance, and moderately hard. It is used mostly for furniture and vehicles. Some is used for refrigerators and kitchen cabinets, baskets, boxes, and crates.

Hemlock, eastern, (*Tsuga canadensis*) grows principally in the Lake States and in the mountains in the eastern part of the United States. The wood is pale buff in color, with a reddish tinge, is moderately light in weight (28 lb per cu ft, air dry) and moderately low in strength. It has a tendency to splinter, is subject to ring shake, and is not decay-resistant. The lumber is nonresinous and holds nails well, and the knots are characteristically small. Eastern hemlock is used largely for framing, sheathing, roofing, and subflooring. In the nominal 2-in. size the stock is cut extra thick, thus partly equalizing the greater strength of some other structural woods. Eastern hemlock lumber is carefully manufactured and graded and consequently can be purchased in quality well suited for general building. A small mount of tamarack (*Larix laricina*), a species heavier and stronger than eastern hemlock, is sawed into lumber and is often sold with eastern hemlock. Most tamarack, however, is utilized in the form of poles, posts, ties, and mine props, reaching the market under its own name.

Hemlock, western, (*Tsuga heterophylla*) grows along the Pacific coast from Alaska to northern California, penetrating farther inland just below the Canadian boundary than elsewhere. This species, which is sold commercially as west coast hemlock, is distinct from eastern hemlock. Western hemlock is a uniform, fine-textured wood and is comparatively free of ring shakes. It is moderately light in weight (29 lb per cu ft, air dry), moderately high in strength properties, usually straight grained, and nonresinous; its many small black knots are ordinarily fixed firmly in place. Its resistance to decay is low. Western hemlock in the common grades is mixed and sold with Douglas fir. It is used largely in house construction for framing, sheathing, and subfloors. Large quantities go also into siding, ceiling, flooring, and shiplap. Other uses are sash, doors, blinds, general millwork, and crossties.

Hickory, pecan, includes **bitternut** (*Hicoria cordiformis*), **nutmeg** (*H. myristicaeformis*), **pecan** (*H. pecan*), and **water hickory** (*H. aquatica*). It is found throughout much of the eastern half of the United States. Density is 45 lb per cu ft, air dry. Although these hickories rank relatively high in strength properties, the true hickories are somewhat superior, especially in shock resistance. Pecan is used for the same purposes as the true hickories, namely, for vehicle parts, tool and implement handles, and special products such as ladder rungs, doweling, and gymnasium apparatus. The bulk of the hickory consumed for these purposes, however, is true hickory. Like the true hickories, pecan is commonly classified as white, which is the sapwood, or red, which is the heartwood. As with the other hickories, color is no criterion of its strength.

Hickories, true, are found throughout most of the eastern half of the United States and are all similar in their properties. The species most important commercially are **bigleaf shagbark** (*H. laciniosa*), **mockernut** (*H. alba*), **pignut** (*H. glabra*), and **shagbark** (*H. ovata*).

Hickory is commonly classified as white, which is the sapwood, and red, which is the heartwood. Color, however, is no criterion of its strength because, weight for weight, sound hickory has the same strength and toughness, regardless of whether it is red, white, or mixed. True hickory is very tough, heavy (51 lb per cu ft, air dry), hard, and strong; the combination of high strength, stiffness, hardness, and shock resistance has not been found in any other native commercial wood. It is low in natural decay resistance and shrinks considerably in drying. Hickory having not more than 20 rings to the inch is generally the strongest, although slow-growth hickory, if heavy, also has high strength properties. True hickory, which is one of the prominent specialty woods, is used principally in the vehicle industry for spokes, rims, poles, and shafts, in the tool-handle industry for ax, pick, sledge, and hatchet handles, and for special products, such as golf-club shafts, ladder rungs, doweling, and gymnasium apparatus.

Larch, western, (*Larix occidentalis*) is native principally to the "Inland Empire." The heartwood is reddish brown, and the sapwood, which usually is not more than 1 in. thick, is yellowish white. In its natural color the wood finishes well, but does not hold paint well. It splits easily and is subject to ring shakes. Knots, although common, are usually small. Resistance to decay is moderate. It is rated as moderately heavy (36 lb per cu ft, air dry), strong, stiff, and moderately good in shock resistance. Western larch and Douglas fir are logged together and are frequently manufactured, graded, and sold together as larch-fir. Western larch is used largely in building construction as rough dimension, small timbers, planks, and boards. Planing-mill products, sash, doors, boxes, and crates take a small portion of it. It is a satisfactory wood for rough construction, and its use as an interior trim is increasing because of its pleasing appearance and ease of finishing.

Locust, black, (*Robinia pseudoacacia*) grows in the Appalachian Mountains from Pennsylvania to northern Georgia. The natural range also includes the southern part of Illinois and Indiana, and part of Arkansas, Oklahoma, and Tennessee. Black locust is one of the heaviest (48 lb per cu ft, air dry) and hardest native woods. It ranks very high in shock-resisting ability and strength. It has a moderately small shrinkage which for its density is very low. The heartwood is very durable. Black locust is subject to wormholes, cross grain, and bird pecks. Checking and splitting generally occur to only a moderate degree. Principal uses are for insulator pins, treenails, wagon hubs, fence posts, mine timbers, and poles.

Magnolia, evergreen, (*Magnolia grandiflora*) grows along the coast from North Carolina to Florida and westward in the Gulf Coast region to Texas and through western Louisiana to southern Arkansas. The range of **cucumber magnolia** (*M. acuminata*) extends from western New York to Alabama, following the Appalachian Mountains, and westward to Illinois and Mississippi, appearing west of the Mississippi River in Arkansas. It is largest and most abundant in the narrow valleys of eastern Tennessee and in the western parts of the Carolinas. The wood of the evergreen and cucumber magnolias resembles that of yellow poplar, but it usually is somewhat harder and heavier (35 and 33 lb per cu ft, air dry, respectively) and often has a light to dark purplish color. A large part of cucumber magnolia and some of the evergreen magnolia lumber are marketed with the lower grades of yellow poplar. During the years immediately preceding the economic depression, an average of about 27 million feet of evergreen magnolia was marketed annually as magnolia, and about one-half million feet of cucumber magnolia was marketed as cucumber. Important uses of these woods include furniture, planing-mill products, finish, siding, and boxes and crates.

Maple. Of the 13 species of maple that grow in the United States, **sugar maple** (*Acer saccharum*) and **black maple** (*A. nigrum*), jointly classed as hard maple, are by far the most important as well as the most abundant. Others of commercial importance are **silver maple** (*A. saccharinum*) and **red maple** (*A. rubrum*), which are commonly called soft maple, and **bigleaf** or **Oregon maple** (*A. macrophyllum*), which belongs in the soft-maple group on the basis of its properties. The commercial maples, as a group, grow throughout the eastern part of the United States, with the exception of bigleaf maple, which appears on the Pacific coast. Hard maple, which has a wide range, is found principally in the Lake States, the Northeast, and in the Appalachians. The heartwood of hard maple is light reddish brown, and its sapwood is white with a slight reddish-brown tinge. The white maple of commerce is the unstained sapwood of sugar maple. The wood of this species is heavy (44 lb per cu ft, air dry), hard, strong, and stiff, has good resistance to shock, and wears well under abrasion, excelling the other maples in these properties. It has moderate shrinkage and uniform texture. The grain is usually straight but sometimes curly, wavy, or birdseye grain occurs. Both silver maple and red maple are lighter in color and not so heavy, hard, or strong as sugar maple. Silver maple is lighter in weight (33 lb per cu ft, air dry) and weaker than red maple (38 lb per cu ft, air dry). The strength properties of bigleaf maple are intermediate between those of silver and red maple. Maple is used for flooring and other planing-mill products, interior trim, and furniture. Large quantities also go into agricultural implements, handles, and vehicle parts.

Oak. All the oaks of commercial importance, about 15 of the 60 or more native species, grow in the eastern half of the United States, especially in the Mississippi Valley and the South. In the lumber trade the oaks are commonly divided into two groups, red oak and white oak, and no attempt at a finer distinction is made in most cases. The common and botanical names of commercial white oak are: **White oak** (*Quercus alba*), **chestnut oak** (*Q. montana*), **swamp chestnut oak** (*Q. prinus*), **swamp white oak** (*Q. bicolor*), **post oak** (*Q. stellata*), **overcup oak** (*Q. lyrata*), and **bur oak** (*Q. macrocarpa*). The common and botanical names of commercial red oak are: **Red oak** (*Quercus borealis*), **swamp red oak** (*Q. rubra pagodaefolia*), **southern red oak** (*Q. rubra*), **pin oak** (*Q. palustris*), **black oak** (*Q. velutina*), **water oak** (*Q. nigra*), and **willow oak** (*Q. phellos*). White oak heartwood is more durable and of lighter color than red oak. Furthermore, the pores in the heartwood of white oak are for the most part plugged with a growth called tyloses, which makes the wood much less permeable to liquids than that of red oak. Oak is commonly sold both plain and quarter-sawed, with advantages in each, among which are more pronounced figure in plain-sawed material and less shrinkage in quarter-sawed material. Oak is heavy (44 lb per cu ft, red, to 47 lb, white, air dry), hard, stiff, and strong. Although there is no important difference in the properties of red and white oak, the oaks like all other species vary in their properties within a single species. Rapidly grown oak is generally stronger, harder, and tougher than slow-growth oak, which is finer grained, softer, and more easily worked. Flooring, interior trim, furniture, motor-vehicle parts, and implements consume a large part of the oak cut; in addition, it is used for cooperage, piling, crossties, and timbers.

Pine, lodgepole, (*Pinus contorta*) is widely distributed throughout the western part of the United States. The wood is light in color, with the heartwood only slightly darker than the sapwood. It is one of the lightest in weight of the yellow pines (29 lb per cu ft, air dry), is moderately low in strength, and has small knots. Lodgepole pine is not durable in contact with the ground, but the sapwood accepts preservative treatment readily. In mature stands, only about 20% of the material is large enough for saw timber; much of the cut is used for poles, mine props, and ties.

Pine, eastern white, (*Pinus strobus*), originally known just as "white pine," is found principally in the Lake States, the Northeastern States, and the Appalachian region. The sapwood is white, and the heartwood ranges from cream to light reddish brown. The wood is moderately light in weight (25 lb per cu ft, air dry), moderately low in strength, and usually straight grained. The soft, uniform texture of the virgin growth has won for it extensive use in building and in millwork. Since its dimensions change little with changes in moisture content and it is easily worked, white pine makes a desirable wood for patterns. The second-growth pine is usually of faster growth and more knotty than old growth. Second growth and the lower grades of virgin-growth pine are largely used for boxes and crates. Virgin growth is becoming scarce.

Pine, red, (*Pinus resinosa*) of the Lake States, although belonging to the yellow pine group, is sold with northern white pine in the lower common grades. It is somewhat coarser in grain and texture, however, has more strongly marked annual rings, is heavier (34 lb per cu ft, air dry) and stronger, and is somewhat more resinous.

Pine, ponderosa, (*Pinus ponderosa*) grows from Washington to the Black Hills and southward in the Rocky Mountain and Pacific coast regions. The wood is moderately light in weight (28 lb per cu ft, air dry), moderately low in strength, and ranks relatively low in shrinkage. It is easy to work, stays in place well, and has a uniform texture, being somewhat comparable in these respects with the white pines. The principal uses of ponderosa pine are for sash and frames, doors, general millwork, building construction, and boxes and crates. Considerable quantities are treated and used for railway ties.

Pine, southern yellow, is a general name for a number of closely related species, chiefly longleaf (*Pinus palustris*), shortleaf (*P. echinata*), loblolly (*P. taeda*), slash (*P. caribaea*), and pond pine (*P. rigida serotina*) which grow in the southern and eastern United States. Except for the fact that the pith often distinguishes longleaf from loblolly, shortleaf, and slash pines, the species cannot be positively distinguished by the wood alone. Southern yellow pine exhibits a considerable range in density and provides material for a wide variety of uses. The denser material (41 lb per cu ft, air dry) provides excellent structural material, whereas the less dense stock (36 lb per cu ft), which is more easily worked, splits less in nailing, often holds a coating of finish better, is superior in thermal insulation, and because of lighter weight may be handled and shipped at lower cost, is used extensively for light buildings, temporary construction, millwork, boxes, and crates. Southern yellow pine is an excellent general utility wood. In general, it has a tendency to check and split, and it does not hold paint well. The sapwood of all the southern pines is easily treated for preservation, and pieces containing a large proportion of sapwood are readily obtained.

Pine, sugar, (*Pinus lambertiana*) is native to California and southern Oregon. It is similar in appearance and properties to eastern white pine but can usually be distinguished by its more conspicuous resin ducts. Density is 25 lb per cu ft, air dry. Sugar pine is the largest of the species of the white pine group, and the bulk of the exceptionally wide, thick stock of soft pine lumber is cut from this species. A large part goes into the manufacture of planing-mill products, such as sash, blinds, and drain boards, and into millwork. It is used interchangeably with eastern white and western white pine for many purposes.

Pine, western white, (*Pinus monticola*), sold commercially as Idaho white pine or Idaho pine, grows principally in northern Idaho, eastern Washington, and western Montana. Western white pine resembles eastern white pine so closely that the clear wood of the two is indistinguishable. Patternmakers state that western white pine is somewhat more difficult to work, although both are regarded highly for their workability. Western white pine is light in color, moderately light in weight (27 lb per cu ft, air dry), and straight grained. It swells and shrinks a little more with changes in moisture content but on the whole compares favorably with eastern white pine and is largely used for the same purposes.

Poplar, yellow, (*Liriodendron tulipifera*) is one of the largest native trees supplying lumber; under favorable conditions it reaches a diameter of 6 to 8 ft and a height of 100 to 160 ft. It grows throughout the eastern part of the United States, with the largest stands in the southern Appalachian Mountains. The sapwood, frequently several inches in thickness, is white. The heartwood is yellowish brown with a greenish tinge. The wood is moderately light in weight (28 lb per cu ft, air dry), straight grained, moderately soft, moderately weak, comparatively uniform in texture, easy to nail because it does not split readily, easy to glue, stays in place well, holds paint and enamel well, is easily worked, and finishes smoothly. Yellow poplar is especially suitable for finish, siding, furniture, and other products that are to be painted or enameled. It is largely used for planing-mill products, furniture, veneer, and panels. The lower grades are used for boxes and crates. Other less important uses are vehicle parts, musical instruments, and car construction. **Cucumber magnolia** (*Magnolia acuminata*) and **evergreen magnolia** (*M. grandiflora*) are sometimes sold with the lower grades of yellow poplar, though they can be purchased under their own names. The wood of these species resembles that of yellow poplar, but it usually is somewhat harder and heavier and often has a light to dark purplish color.

Redwood. The commercially important stands of redwood (*Sequoia sempervirens*) are chiefly confined to a narrow belt, 10 to 30 miles wide, that extends from southern Oregon to within a few miles of San Francisco. The redwood forest in a small area south of San Francisco is also of commercial importance. The heartwood of redwood varies in color from cherry to dark mahogany, and the sapwood, which is very narrow, is almost white. Many of the redwoods are extremely large, individual trees commonly reaching diameters of 5 to 10 ft. Exceptional trees attain a diameter of 20 ft or more. Such size permits a high percentage of clear lumber, and unusually wide clear boards are easily obtained. Redwood is moderately light in weight (28 lb per cu ft, air dry) and moderately strong. Because of its high durability, the heartwood is especially valuable where resistance to decay is important. It has a low shrinkage, stays in place well, and is not difficult to work. It is used for sash, doors, frames, siding, and interior and exterior finish, and is valuable also for posts, crossties, tanks, pipes, flumes, greenhouses, and other service in which the structural material is subject to conditions that favor decay. It holds paint well. Redwood is also used as structural timber for highway bridges, trestles, mill roofs, and similar structures.

Spruce, "eastern," is a term which includes three species: **red** (*Picea rubra*), **white** (*P. glauca*), and **black spruce** (*P. mariana*). White spruce and black spruce grow principally in the Lake States and New England, and red spruce in New England and the Appalachian Mountains. All three species have about the same properties, and in commerce no distinction is made between them. The wood dries easily, stays in place well, is moderately light in weight (28 lb per cu ft, air dry) and easily worked, and has a moderate shrinkage and a moderate degree of strength, stiffness, toughness, and hardness. Eastern spruce is not resistant to decay. The wood is light in color, and there is little difference between the heartwood and sapwood. Eastern spruce is used principally for framing material and general millwork. Large quantities are also used in boxes and crates.

Spruce, Sitka, (*Picea sitchensis*) grows in a narrow strip, seldom more than 40 miles wide, along the pacific coast from Alaska to Northern California. The wood is light in weight (28 lb per cu ft, air dry) and has a moderate degree of hardness, stiffness, toughness, and strength. It ranks high in strength for its weight. On this account and also because it can be obtained in clear, straight-grained pieces of large size and uniform texture, Sitka spruce is the favored wood for airplanes. The wood dries easily, stays in place well, has a moderate shrinkage and is easily worked. It is not resistant to decay. It is used for sash, doors, siding, ceiling, flooring, exterior and interior finish, and aircraft construction. Large quantities go into boxes, crates, and ladders.

Sycamore (*Platanus occidentalis*) grows widely in the eastern half of the United States, but the greater portion comes from the bottom lands along the Mississippi River and its tributaries. Sycamore is moderately heavy (34 lb per cu ft, air dry) and moderately strong. The heartwood is reddish brown, and the sapwood is somewhat lighter in color. In quarter-sawed sycamore the rays are conspicuous, but the plain-sawed lumber has little figure. Seasoning the wood without warping is difficult, especially when it is plain-sawed. Sycamore is used principally for interior trim and fancy paneling. Other uses are baskets, boxes and crates, and furniture.

Tupelo, water, (*Nyssa aquatica*) is found principally in the swampy regions of the South. **Black gum** (*N. sylvatica*) is native to all states east of the Mississippi River. In the South, it grows as far west as Texas. Water tupelo and black gum are sold both under their respective names and in mixture as one or the other, because there is no way of positively identifying the wood of the two species. These species were not cut for lumber to any great extent until about 25 years ago, at which time better means of handling and utilization were developed. The lumber of water tupelo and black gum is largely sapwood, which is grayish white when dry, soft, of fine texture, moderately heavy (35 lb per cu ft, air dry), and moderately strong, but is cross-grained, tends to warp, and is difficult to split. It is used largely for boxes and crates, flooring, inside finish, furniture, and vehicle parts. For factory floors, bridge flooring, and platforms subjected to heavy wear it has proved very satisfactory, but it requires preservative treatment when used under conditions that favor decay. The wood cut from the true black gum tree is, on the average, harder and stronger than that of the true water tupelo. Where a pretense is made commercially of differentiating between black gum and water tupelo lumber, it is usually on the basis that the harder material passes as black gum and the softer as water tupelo, even though actual species lines are disregarded in segregation.

Walnut, black, (*Juglans nigra*), one of the most beautiful native woods, is found in commercial quantities chiefly in Missouri, Iowa, Illinois, Indiana, Ohio, Kentucky, and Tennessee, although it grows to some extent from New England to Texas. The heartwood, which is brown, varies from light to dark in color. The sapwood is nearly white. The wood is heavy (38 lb per cu ft, air dry), hard, strong, and stiff. It stays in place well, takes stain and other finishes exceedingly well, and will also take a good polish. Besides this, it is easily worked and glues satisfactorily. Black walnut is used largely for cabinet work, furniture, interior finish, and gunstocks. Figured and higher-grade black walnut is cut into veneer and used as faces in plywood and panel construction. **Butternut** (*Juglans cinerea*) is related to walnut botanically and is sometimes actually called white walnut, but the wood is radically different in most respects. Density is 27 lb per cu ft, air dry. Butternut is soft and has low strength properties, but the grain and color are attractive and the wood is used to a limited extent for decorative purposes, particularly for veneer.

IMPORTED WOODS. Balsa (*Ochroma lagopus*) is native to tropical America. It is one of the lightest commercial woods but has a wide range in density. The specific gravity, based on weight when oven-dry, may vary from about 0.05 to 0.40 (3 to 25 lb per cu ft, air dry), so that for some uses the wood is selected or classified for density. The wood is pale gray or slightly brownish in color. Uses include thermal insulation, cushioning supports for machinery, and, when waterproofed, life preservers, rafts, and floats. It also provides an excellent core for sandwich construction.

Brazilian araucaria (*Araucaria angustifolia*) or Parana pine is native to southern Brazil and adjacent Paraguay and Argentina. The sapwood is yellowish and the heartwood light brown, resembling medium-colored bald cypress. The heartwood may contain bright red streaks. The average weight when the wood is air dry is about 33 lb per cu ft. Uses include construction lumber, matches, cooperage, turned products, paper pulp, shingles, shipping containers, furniture, interior trim, flooring, and veneer.

Crabwood or *Cedro macho* (*Carapa* species, chiefly *C. guianensis*) is native to tropical America. It should not be confused with Spanish cedar, which is also sometimes called

Cedro macho. The heartwood varies from pinkish to dark reddish brown, somewhat resembling walnut in appearance. The average weight per cubic foot is about 42 lb. The wood is used for cabinet work, furniture, and interior fittings.

Ebony (*Diospyros* species) has a naturally dark or black heartwood. The most valued species are native to India and Ceylon, but the material is also found elsewhere in the tropics. The wood weighs about 70 lb per cu ft, air dry. The dark wood is valued for its color and because it turns and polishes well, making it suitable for cabinet work, musical instruments, inlays, handles, and fancy articles.

Greenheart (*Ocotea rodiaei*) is found chiefly in British Guiana. The color of the heartwood varies from light to dark olive or nearly black. The wood weighs about 65 lb per cu ft, air dry. The heartwood is resistant to decay and termites and is especially valued for ship and marine construction.

Khaya (*Khaya* species) or so-called African mahogany is native to tropical West Africa. The heartwood is pale red to dark reddish brown, often purplish. The average weight is about 31 lb per cu ft, air dry. The principal uses are furniture, fixtures, and interior finish, much in the form of veneer.

Lignum vitae (usually *Guaiacum officinale* but sometimes also *G. sanctum*) is native to tropical America. The heartwood is olive-brown or bluish to dark brown or nearly black. It weighs about 78 lb per cu ft and is one of the hardest, heaviest, and most durable woods. Lignum vitae has an interlocked grain and an oily resinous content which acts as a natural lubricant. Important applications are water-lubricated bearings for ship propeller shafts and pumps, bearings, pulley sheaves, small turnings, mallet heads, furniture casters, tool handles, stencil blocks, and band-saw guides.

Mahogany (*Swietenia* species) is native to the West Indies and tropical America. The heartwood is reddish brown. Unlike most species, the radial and the tangential shrinkages are about equal. The relatively small shrinkage and easy working qualities contribute to making mahogany an excellent pattern wood. It weighs about 32 lb per cu ft, air dry. Mahogany is highly valued for cabinet work, interior finish, furniture, veneer, boats, and patternmaking.

Okoume (*Aucoumea Klaineana*) or Gaboon is native to West Africa. The pink or pinkish-brown heartwood has an average weight of about 29 lb per cu ft, air dry. Principal uses are veneer, interior woodwork, furniture, and boats.

Lauan or so-called Philippine mahogany comprises woods chiefly from the genera *Shorea Parashorea*, *Pentacme*, and *Tarrietia* of the Philippine Islands. The color of heartwood varies from dark red or reddish brown to a lighter reddish gray. The average weight of these woods is about 35 lb per cu ft. The principal uses in the United States are for cabinet work, furniture, boats, and interior trim.

Primavera (*Cybistax donnellsmithii*) is native to tropical America. The heartwood ranges in color from creamy or yellowish white to brownish with occasional rose-pink streaks. The average weight is about 30 lb per cu ft, air dry. The chief uses are for "blonde" furniture, cabinet work, and interior trim.

Sapele (*Entandrophragma* species), also called Sapele mahogany, is native to Central and West Africa. The heartwood of these species is dark or brownish red and often more purplish than the wood of *Khaya*. Sapele weighs about 40 lb per cu ft, air dry. The principal uses are for veneer, cabinet work, interior trim, and boats.

Teak (*Tectona grandis*) is found naturally in commercial quantities in India, Burma, Siam, French Indo-China, and Java, but plantations have also been established in many parts of the world. The yellowish or grayish brown heartwood is highly resistant to decay, termites, and marine borers. Teak from Burma averages about 43 lb per cu ft, air dry, and has relatively low shrinkage. It is especially valued for ship decking, furniture, and interior finish.

DECAY RESISTANCE. The development of fungi which cause decay in wood depends on suitable temperature, moisture conditions, and air supply. When any of these conditions is lacking, wood will last indefinitely. Hence, wood kept either constantly dry or continually submerged in water does not decay, regardless of species of wood or presence of sapwood.

Under conditions favorable to decay, species with natural resistance to decay should be chosen, or preservative treatment should be resorted to, or both precautions should be taken. For information on preservative treatment, see Section 25, Article 10. Different woods vary greatly in their natural decay resistance, but even in durable woods the decay resistance lies in the heartwood. When untreated, the sapwood of practically all species has low resistance to decay and usually has a short life under decay-producing conditions. Individual pieces of wood of a species may also vary from others of the same species in durability. The estimated classification of a number of species with respect to decay resistance follows:

1. Heartwood very durable even when used under conditions favoring decay: Cedar (Alaska yellow, eastern red, northern white, Port Orford white, southern white, western red); chestnut; bald cypress; black locust; Osage orange; redwood; black walnut; Pacific yew.

2. Heartwood nearly as durable as that of species listed as very durable: Douglas fir (dense); honey locust, white oak, southern yellow pine (dense).

3. Heartwood of intermediate durability: Douglas fir (unselected); sweet gum; western larch; southern yellow pine (unselected); tamarack.

4. Heartwood less durable than intermediate group: Commercial white ash; beech; birch (sweet, yellow); hemlock (eastern, western); hickory; sugar maple; red oak; spruce (black, Engelmann, red, Sitka, white).

5. Heartwood low in durability when used under conditions favorable to decay: Aspen; basswood; cottonwood; commercial white fir; black willow.

MODIFIED WOOD AND WOOD-BASE MATERIALS. There have been developed various modified forms of wood by means of exposure to high temperatures and pressures and/or resin treatment. A brief description of these products, which have greatly modified properties and many special uses, follows:

Impreg is the name given resin-treated wood that has not been compressed. A moderate increase in weight results due to the resin, accompanied by some improvement in compressive strength, but more significantly by greatly increased dimensional stability (reduced shrinking and swelling), decay resistance, electrical resistance, and acid resistance. These improved properties are accompanied by decreased toughness of the wood. A vital point in the improved process is impregnation with a phenolic resin-forming material that has an affinity for wood and penetrates the finer cell structure prior to polymerization.

Compreg is the general class of densified product comprising resin-treated and compressed wood, usually in the form of a laminated material. With resin impregnation of about 20% (based on the combined weight) and full compression, the density is about 1.35 to 1.40. The modulus of rupture and tensile strength parallel to the grain are on the order of 30,000 to 40,000 psi, with modulus of elasticity in the range of 3,000,000 to 4,000,000 psi. Marked antishrink efficiency is obtained by impregnating the wood with stabilizing phenolic resins as in the case of impreg.

Staypak is the densified product resulting when wood is compressed under conditions of moisture content and temperature that cause sufficient flow of lignin to relieve internal stresses and thus avoid the springback under the moisture exposure condition inherent in ordinary compressed wood. No resin is employed when staypak is made from solid wood. The density is about 1.35 to 1.40, approaching that of wood substance. Although not dimensionally stabilized like compreg, staypak is about twice as tough and has somewhat higher values in tension, flexure, and modulus of elasticity.

Papreg is the name given to resin-treated, compressed, laminated paper. Its density when fully compressed and with a resin content of 35% is about 1.40. Significant improvements in tensile and compressive strength and stiffness have been attained by improvements in the paper base used. Papreg has a tensile strength of 35,000 to 40,000 psi for parallel-laminated constructions and can be processed with varying properties to meet special requirements. It can be moderately post formed. Research has shown the feasibility of laminating with pressures as low as 50 psi, greatly facilitating molding of special shapes.

PLYWOOD (see also Section 25, Article 8) consists of a combination of three or more layers of veneer, usually glued together with the grain of alternate plies at right angles. Thus, although special properties result from the method of construction of plywood, the mechanical properties are complicated not only by the orthotropic structure of the wood itself but also by the arrangement of the plies. Compared with solid wood, the chief advantages of plywood are an equalization of strength properties along the length and width of the panel, greater resistance to checking and splitting, and greater dimensional stability with changes in moisture content.

Because plywood can be made with any desired number of plies from veneer of any desired thickness and species, or with any combination of thicknesses and species, it presents a versatility that affords almost unlimited choice in design.

18. DESIGN OF WOOD STRUCTURES

Natural and dressed sizes of American standard yard lumber and timber are listed in Table 1.

BASIC UNIT STRESSES for **clear timber** in bending, tension parallel to grain, compression, and shear are given in Table 2. For design with other than clear material, cer-

				24 × 30	23 1/2 × 29 1/2

tain of these basic values must be adjusted downward, and for seasoned material used under dry conditions of service certain of these values may be increased. The amount of the reduction necessary, or of the increase permissible, depends on the property, on the size of timber, and on the use.

Structural grade and use factors as they relate to the modification of the basic unit stresses of Table 2 are presented in Table 3. As an example, the allowable stress for extreme fiber in bending for a grade of beams and stringers having defects that reduce the strength by one-fourth would be three-fourths of the value in Column 2, Table 2, for the species in question. For detailed information on methods of evaluating the **grade-strength ratio** timbers and for modifying basic stresses, see *Tentative Methods for Establishing Structural Grades of Lumber*, ASTM Designation D245-49T. The principal lumber associations have adopted stress grades applicable to the species used for structural purposes that they produce, and stress-graded lumber is commercially available.

BEAM DESIGN. To apply the bending formula to wood beams, it is necessary to consider the form factor.

Form Factors. When the height of a beam of rectangular cross section is increased, the modulus of rupture decreases slightly. This decrease should be considered in accurate comparisons of beams of different heights. The fractional decrease is the difference between unity and the form factor of the beam. A form factor is the ratio of the unit strength value of a beam of structural size to the corresponding unit value for a beam 2 by

* These stresses are applicable with certain adjustments to material of any degree of seasoning.

2 in. in cross section. The form factor is already included in the safe stresses in bending and for ordinary purposes need not be considered further.

The form factor, F, is inserted in the usual beam formula as follows:

$$M = \frac{FsI}{c}$$

in which M represents the bending moment; s, the unit stress due to the bending moment upon the fiber most remote from the neutral axis; I, the moment of inertia of the cross section about the neutral axis; and c, the normal distance from the neutral axis to the outermost fiber. For a rectangular beam, this formula reduces to

$$M = \frac{Fsbd^2}{6}$$

in which b represents the breadth and d the depth of the beam. The value of F is calculated by means of the formula

$$F = 1 - 0.07\left(\sqrt{\frac{d}{2}} - 1\right)$$

in which d is the depth of the beam. The value of F becomes unity when d is equal to 2. All standard bending tests on clear wood are made on beams 2 by 2 in. in cross section, and the formula for F was accordingly based on the value of the factor, unity, for a 2-in. height.

In I and box beams it is important to consider the form factor, since the safe extreme fiber stresses for wood beams apply directly only to beams of rectangular section. The reduction factor for the modulus of rupture may be obtained by substituting in the following empirical formula:

$$F = 0.50 + 0.50\left(\frac{K(t_2 - t_1)}{t_2} + \frac{t_1}{t_2}\right)$$

in which F represents the form factor for modulus of rupture; K, a coefficient depending upon the ratio of flange depth to total depth of beam (see Table 4); t_1, the thickness of

Table 3. Table Showing Which Working Stresses Are and Which Are Not Modified by Each of the Grade and Use Factors *

(U. S. Forest Products Laboratory)

Kind of Working Stress	Size Classification	GRADE OR USE FACTOR					
		Grade	Rate of Growth	Density	Seasoning	Conditions of Exposure	Duration of Load

	Posts and timbers	No	No	No	No	No	No

* Modification for grade (Col. 3) is accomplished by application of the grade strength ratio. Modifications for rate of growth and density (Cols. 4 and 5) are shown under the appropriate species in the basic stresses of Table 2. Modifications for seasoning, conditions of exposure, and duration of load (Cols. 6, 7, and 8) are to be made by the designer to fit the particular conditions for which the design is made.

† Modification for seasoning in current commercial practice is accomplished by liberalizing defects in grade rather than increasing working stress.

‡ It is recognized that timber design in general should be on a more conservative basis when decay hazard is present. However, the specific amount of stress reduction for the decay hazard is left for the designer to determine on the basis of the conditions applicable in each particular instance.

the web of an I beam or the combined thickness of the two webs of a box beam; and t_2, the overall width of beam.

The form factor for fiber stress at proportional limit is not the same as the modulus of rupture form factor. It is obtained by substituting in the formula

$$F_1 = 0.58 + 0.42\left(\frac{K(t_2 - t_1)}{t_2} + \frac{t_1}{t_2}\right)$$

in which K has the values given in Table 4.

PLYWOOD DESIGN. The following recommended methods for calculating the strength and stiffness of plywood (see Table 5) are an abridgment and simplification of more elaborate mathematical formulas that have been developed. Although they should be regarded as approximate, they may be considered sufficiently accurate for most structural design purposes where *buckling of the plywood does not occur*. If these approximate methods are applied to structures or structural elements so proportioned that the plywood will buckle, the resulting values will be higher than those which can be expected of the structure.

Appropriate unit stresses for Table 5 may be obtained from Table 2 as follows:

Clear Plywood without Defects Use values from Table 2 with or without modification as directed in the last column of Table 5.

Plywood with Defects. When defects are present, reduce the foregoing stresses according to the structural grade ratio. If the defects reduce the strength by one-fourth, multiply the foregoing stresses for clear plywood by $^3/_4$, etc., except compression perpendicular to grain and modulus of elasticity, which are not affected by grade.

Plywood Used in Dry Locations. The unit stresses for extreme fiber in bending, compression parallel to grain, and compression perpendicular to grain may be increased by 25%. No increase for seasoning is provided for horizontal shear or modulus of elasticity.

BASIC FACTS. Durability. Wood, when not subjected to such deteriorating agencies as decay, will last indefinitely. In Europe, many wood structures and structural units that are centuries old still exist.

Decay of wood is caused by fungi, of which there are many varieties. Aside from food, three essentials to the development of fungi are air, suitable temperature, and favorable moisture content. Wood that is completely submerged in water does not decay because the necessary air is lacking. Wood with a moisture content constantly below about 20% does not decay because insufficient moisture is available for decay-producing organisms. The so-called "dry-rot" develops in timber that is apparently below such a moisture content because this fungus is capable of conducting the needed moisture from sources outside the timber itself.

The natural heartwood of some species is very resistant to decay, whereas the sapwood of all species is nondurable when exposed to conditions favoring decay. Examples of the most durable species are redwood, Western red cedar, and bald cypress.

Decay resistance of wood can be greatly increased by impregnation with wood-preserving chemicals, such as creosote. (See Section 25, Article 10.)

The heartwood of most species of wood is more resistant to impregnation with preservatives than sapwood. Hence, sapwood is generally to be preferred to heartwood for the outer portion of timbers that are to be treated.

Creosote in itself does not affect the strength properties of wood, but severe methods of treatment to obtain desired impregnation and penetration may seriously reduce the strength.

Untreated timber should not be completely imbedded in masonry; ventilation space should be provided at the ends of joists or girders supported in masonry walls to avoid decay conditions.

Kiln drying affords more rapid seasoning than air drying; properly kiln-dried wood is fully equal in strength to air-dried material. (See Section 25, Article 6.)

Appearance of the wood is not a reliable criterion of the effect of drying or treating process upon its strength.

Specific gravity of wood substance itself is practically constant for all species, being about 1.53. Differences in the bulk density of different species are hence due to differences in the amount of wood substance present.

Density and Strength. There is a general relation between the density of wood and its strength properties, the strength increasing with density. Some properties, such as compressive strength, increase as the first power of density, and others, such as hardness, vary as the $2\ ^1/_4$ power among species.

Summer wood is in general appreciably denser than **spring wood,** and hence in some species, such as southern yellow pine and Douglas fir, the proportion of summer wood may

Table 4. Values of K in the Form Factor Formula

Ratio of Depth of Compression Flange to Depth of Beam	Values of K	Ratio of Depth of Compression Flange to Depth of Beam	Values of K
0.10	0.085	0.60	0.875
0.15	0.155	0.65	0.920
0.20	0.230	0.70	0.950
0.25	0.315	0.75	0.970

0.35	0.490	0.85	0.995
0.40	0.575	0.90	0.998
0.45	0.660	0.95	1.000
0.50	0.740	1.00	1.000
0.55	0.810		

Table 5. Design Method and Allowable Stresses for Plywood [*]

(U. S. Forest Products Laboratory)

Property	Direction of Stress with Respect to Direction of Face Grain	Area to Be Considered	Unit Stress to Be Used
Tension	Parallel or perpendicular	Parallel plies only [†]	Unit stress for extreme fiber in bending
	±45°	Full cross-sectional area	One-sixth unit stress for extreme fiber in bending
Compression	Parallel or perpendicular	Parallel plies only [†]	Unit stress in compression parallel to grain
	±45°	Full cross-sectional area	One-third unit stress in compression parallel to grain
Bearing at right angles to plane of plywood		Loaded area	Unit stress in compression perpendicular to grain
Load in bending	Parallel or perpendicular	Bending moment $M = KSI/c$, where S = unit stress for extreme fiber in bending; I = moment of inertia computed on basis of parallel plies only; c = distance from neutral axis to outer fiber of outermost ply having its grain in the direction of the span; $K = 1.50$ for three-ply plywood having the grain of the outer plies perpendicular to the span; $K = 0.85$ for all other plywood.	Unit stress for extreme fiber in bending
Deflection in bending	Parallel or perpendicular	Deflection may be calculated by the usual formulas, taking as the moment of inertia that of the parallel plies plus one-twentieth that of the perpendicular plies. (When face plies are parallel, the calculation may be simplified, with but little error, by taking the moment of inertia as that of the parallel plies only.)	Unit value for modulus of elasticity
Deformation in tension or compression	Parallel or perpendicular	Parallel plies only [†]	Unit value for modulus of elasticity
Shear through thickness	Parallel or perpendicular	Full cross-sectional area	Double unit stress in horizontal shear
	±45°	Full cross-sectional area	Four times unit stress in horizontal shear

---

[*] The suggested simplified methods of calculation apply reasonably well with usual plywood types under ordinary conditions of service. It is recognized, however, that they are not entirely valid for all types of plywood and plywood constructions, or for all spans and span-depth ratios. Also, the methods given are not applicable to structures so proportioned that the plywood is in the buckling range, in which event the results will be too high.

[†] By "parallel plies" is meant those plies whose grain direction is parallel to the direction of principal stress.

(*Table continued on p. 5-88*)

Table 5. Design Method and Allowable Stresses for Plywood *—*Continued*
(U. S. Forest Products Laboratory)

Property	Direction of Stress with Respect to Direction of Face Grain	Area to Be Considered	Unit Stress to Be Used
Shear in plane of plies	Parallel or perpendicular	Full shear area. 1. Plywood beams. Horizontal shear: 	1. Three-fourths unit stress in horizontal shear
		Area of contact between plywood and flange or framing member. 2. I or box beams with plywood webs. Shear between plies of web or between web and flange:  	2. Three-eighths unit stress in horizontal shear
		3. Panels having plywood covers stressed in compression or tension, or both. Shear between plies or between cover and framing members when depth of member exceeds twice its width and end headers are used or when depth is not more than twice the width and no headers are used. A. Interior framing members: 	3. A. Three-fourths unit stress in horizontal shear
		B. Framing members at edge of panel: 	B. Three-eighths unit stress in horizontal shear
	±45°	Area of contact between plywood and flange or framing member. 1. I or box beams with plywood webs. Shear between plies of web or between web and flange:  	1. One-half unit stress in horizontal shear
		2. Panels having plywood covers stressed in compression, or tension, or both. Shear between plies or between cover and framing members when depth of member exceeds twice its width and end headers are used or when depth is not more than twice the width and no headers are used. A. Interior framing members: 	2. A. Unit stress in horizontal shear
		B. Framing members at edge of panel: 	B. One-half unit stress in horizontal shear

be used as a criterion of strength. The so-called "density rule" in the structural grading of these species is based on this principle and allows a $^1/_6$ increase in working stress.

Density Variation. There is considerable variation in the density and strength of individual pieces of wood from a single tree, and also variation among different trees of a species. The estimated probable variation in bulk density of an individual piece from the average for the species is about 8%.

Moisture in wood in the green state is in part adsorbed by the cell walls and in part held as free water in the cell cavities. As wood dries, the cell walls do not give off moisture until the adjacent cell cavities are empty. The condition in which the cell walls are fully saturated and the cell cavities are empty is known as the "fiber-saturation point." It varies from 25 to 35% moisture content but for general purposes is accepted as 30%.

Wood is hygroscopic and, when left exposed a sufficient time to any given temperature and humidity conditions, will come to constant weight. The amount of moisture held in adsorption and as free water is proportional to the amount of wood substance present and is expressed as a percentage of the weight of the oven-dry wood, as "the moisture content." There is a definite relationship between the moisture content of wood and relative humidity at any given temperature. Wood held in a room controlled to a temperature of 75 F and a relative humidity of 64% will come to equilibrium at 12% moisture content.

Green wood begins to shrink across the grain when the moisture content is lowered below the fiber-saturation point. Wood shrinks and swells across the grain with the lowering or raising of the moisture content, for moisture content values below fiber saturation. The longitudinal shrinkage of normal wood is negligible for most uses.

Increase in strength of wood in small sizes begins when the wood is dried below the fiber-saturation point. For the properties affected, the change in strength is related to the change in moisture content, the amount of change varying with the property. For timbers in structural sizes, the increase in strength is partially or largely offset by seasoning defects, depending on the size and grade.

Grade. Some dimension grades of lumber are based on appearance characteristics which are not definitely related to strength. Structural timber grades are based on classification with respect to size and location of defects, for the express purpose of permitting assignment of working stresses. When a structural timber is resawn, the grade of the smaller stock produced bears no relation to the grade of the original structural timber.

Rate of growth as indicated by the width of the annual rings, although of some assistance in appraising quality, is not a reliable criterion of strength. Density is a much better guide to strength.

Change from sapwood to heartwood in a tree does not affect the strength properties. The conditions of growth that prevail when the wood is formed determine the density and the strength. Hence, specifying "heartwood" or "sapwood" does not in itself assure superior strength but may be desirable for other reasons, such as "heartwood" for decay resistance, or "sapwood" for ease of preservative treatment.

Dead Trees. Sound wood from trees killed by fire, insects, or fungi is suitable for structural uses if not unduly checked.

Grain. Wood may be treated mathematically as an orthotropic material with three principal axes of symmetry, longitudinal, radial, and tangential. Consequently, the "grain" directions play an important part in design and make wood more complicated than isotropic materials. From the standpoint of close design, wood has three moduli of elasticity, three moduli of rigidity, and six Poisson's ratios.

Camber. Good design practice suggests consideration of adequate camber for roof trusses and like structures where sag is undesirable.

Safety Factor. Because the ratio of the ultimate strength of small clear pieces of wood in bending to the recommended fiber stress for design of structural timbers is on the order of 4, or more, it cannot be assumed that this is the true factor of safety under continued loading. The true factor of safety for the poorer pieces is less than 2, when allowances are made for variability, duration of stress, size factor, and grade.

Thermal expansion of wood is so small as to be unimportant in ordinary usage.

FABRICATED MATERIALS

1. PLATES, SHEETS, BARS, AND RODS

WEIGHT OF PLATE AND SHEET. Table 1 gives the specific gravity and density of the common plate and sheet materials. Column 6 gives the weight in pounds per square foot of plate 1 in. thick, from which the weight of any other thickness is found by multiplying by the thickness t. A conveniently remembered rule is that an iron or steel plate 1/4 in. thick weighs approximately 10 lb per sq ft.

Table 1. Weight of Plates, Bars, Rods, and Spheres

1	2	3	4	5	6	7	8	9	10
Material	Specific Gravity	Density		Relative Weight to Steel	Plate, lb/sq ft, $t\times$	Bar and Rod, lb/ft			Spheres, lb, $D^3\times$
		Lb/cu ft	Lb/cu in.			Square or Flat, s^2 or $bt\times$	Hexagonal, $f^2\times$	Round, $D^2\times$	
Magnesium (Dowmetal M)	1.76	110	.064	0.224	9.2	0.76	0.66	0.60	.0333
Aluminum (24S alloy)	2.77	173	.100	0.353	14.4	1.20	1.14	0.94	.0524
Zinc	7.14	446	.258	0.910	37.2	3.10	2.68	2.43	.135
Cast iron	7.22	450	.260	0.918	37.5	3.12	2.71	2.45	.136
Wrought iron	7.70	480	.278	0.980	40.0	3.33	2.89	2.62	.145

Lead	11.35	708	.410	1.445	59.0	4.92	4.26	3.86	.215

(s = side of square, inches; b = width of flat, inches; t = thickness of flat, inches; f = width across flats of hexagon, inches; D = diameter, inches.)

In calculating areas of square and round plates and sheets, the tables on pp. 28-26 to 28-42, and p. 28-46, will be found helpful.

WEIGHT OF BARS AND RODS. Columns 7, 8, and 9 of Table 1 list coefficients from which the weights of flat, hexagon, and round bars may be calculated by multiplying by the dimensions at the heads of the columns. Actual weights of steel bars and rods are given in Tables 2, 3, and 4; for other materials, the values in Tables 2, 3, and 4 should be multiplied by the constants in column 5 of Table 1. Octagon bars weigh 17.16% less than square bars of the same width across flats.

WEIGHT OF TUBING. To find the weight per foot of tubing, the coefficients in column 9 of Table 1 should be multiplied by $(D^2 - d^2)$ or $4t(d + t)$ or $4t(D - t)$, where d is the bore of the tube, D is the outside diameter, and t is the wall thickness, all in inches.

STRUCTURAL SHAPES illustrated in Fig. 1 are available in a wide range of sizes in steel and aluminum; many are also available as magnesium extrusions. For shapes and sizes available as well as detail dimensions and section properties, see Eshbach's *Handbook of Engineering Fundamentals*, John Wiley and Sons, 1936, and the handbooks issued by the Bethlehem Steel Co., Carnegie Illinois Steel Corp., Aluminum Company of America, Dow Chemical Co., and other manufacturers.

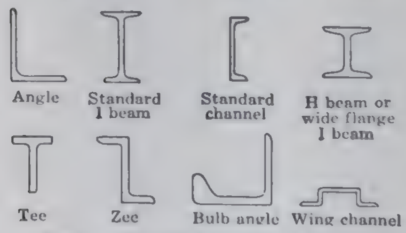

Fig. 1. Standard structural shapes.

Table 2. Weights of Rectangular Sections—Steel

(Pounds per lineal foot. For other materials, multiply by coefficients in column 5 of Table 1.)

2. WIRE GAGES AND SHEET METAL GAGES

The two wire gages in most extensive use in the United States are the American Wire Gage, also known as the Brown & Sharpe Gage, and the United States Steel Wire Gage more commonly called simply Steel Wire Gage.

Three other wire gages have remained in use but are now almost obsolete. These are the Birmingham Wire Gage, the Stubs Steel Wire Gage, and the Old English Wire Gage. There are also certain special gages, as the drill and screw rod gages and the music wire gage. The most frequently used special gage is the Birmingham Gage, sometimes called the Stubs Wire Gage. Its use in this country has been practically limited to large telegraph and telephone companies and certain departments of the Government. The Treasury Department used this gage for collection of duties on imports of wire.

As there are many gages differing from each other, and since even the thicknesses of a certain specified gage, as the Birmingham, are not assumed the same by all manufacturers, *orders for sheets and wires should always state the weight per square foot, or the thickness in thousandths of an inch.*

THE AMERICAN WIRE GAGE (Brown & Sharpe Gage) is practically the only gage used for copper and aluminum wire and, in general, for all wire in electrical work. (See Table 5.) Sizes of stranded conductors larger than No. 0000 AWG are specified by the cross section in circular mils (see below). The American Wire Gage also is used for sheets of copper, aluminum and other nonferrous metals. Wire diameters of successive gage numbers are in geometric progression, the ratio being $92^{1/39} \approx 1.1229$.

CIRCULAR MIL. A circular mil is the area of a circle 1 mil (0.001 in.) in diameter; hence the area of any circle in circular mils is equal to the square of its diameter in mils.

THE STEEL WIRE GAGE is the same gage which formerly was known by the names of Washburn & Moen Gage and the American Steel & Wire Co. Gage. This gage, with certain of its sizes rounded off to even thousandths of an inch, is identical with the Roebling Gage. It is used for practically all steel wire in the United States. (See Table 5.)

Although the American and Steel gages are practically standard and have official although not legal sanction, the trend of practice is toward the specifying of all sizes of wire and sheet material in decimals of an inch rather than by gage numbers.

STUBS STEEL WIRE GAGE has a somewhat limited use for tool steel wire and drill rods. It should not be confused with the Birmingham Wire Gage, which is sometimes known as Stubs Iron Wire Gage. (See Tables 5 and 6.)

THE STANDARD WIRE GAGE, also known as the New British Standard, the English Legal Standard, or the Imperial Wire Gage, is the legal standard of Great Britain for all wires. It was constructed by so modifying the Birmingham Wire Gage that the differences between successive diameters were the same for short lengths. (See Table 5 under British Standard Wire Gage.)

MUSIC WIRE GAGE. Several gages are in use for music wire. Two of the most extensively used are given in Table 5. For data on others, see *Machinery's Handbook*, the Industrial Press.

EDISON WIRE GAGE. The size of a wire on this gage equals its cross-sectional area in circular mils divided by 1000. This gage is now rarely used.

The U. S. STANDARD GAGE FOR SHEET AND PLATE IRON AND STEEL. An Act of Congress in 1893 established the Standard Gage for sheet iron and steel. It is based on the fact that a cubic foot of iron weighs 480 lb.

A sheet of iron 1 ft square and 1 in. thick weighs 40 lb, or 640 oz, and 1 oz in weight should be $^1/_{640}$ in. thick. The scale has been arranged so that each descriptive number represents a certain number of ounces in weight and an equal number of 640ths of an inch in thickness.

According to the law, on and after July 1, 1893, the new gage shall be used in determining duties and taxes levied on sheet and plate iron and steel; and in its application a variation of $2\,^1/_2$% either way may be allowed.

The U. S. Standard Gage for sheet and plate iron is a *weight* gage, not a thickness gage, and is based on the following assumptions:

	Iron	Steel
Specific gravity	7.7	7.854
Weight per cubic foot	480.0	489.6
Weight per cubic inch	0.2778	0.2833

It applies to iron only; for steel the thickness would vary as 480/489.6.

ZINC GAGE is a special gage applied to sheet zinc (see Table 3, p. 4-63). Its use is discouraged, actual thickness in thousandths of an inch being preferred.

METRIC WIRE GAGE number is ten times the diameter in millimeters.

TWIST DRILL GAGE numbers are listed in Table 7. Use of these gage numbers is discouraged in favor of the American Standard series of drill sizes, which consists of 116 decimal-size drill diameters, ranging from 0.0156 to 0.500 in., inclusive. See ASA B5.12-1940, *Twist Drills*, also Table 1 in Article 23, Section 23, in this volume.

Table 7. Twist Drill and Steel Wire Gage

(Manufacturers' standard)

				.437	195–215

for details of composition, tolerances, etc. *Carbon steel valve spring quality* wire (ASTM A230-47) is a 0.60 to 0.70% carbon steel, hardened and tempered to the desired physical properties. *Music spring wire* (A228-41) is a 0.70 to 1.00% carbon steel, cold drawn to produce the desired physical properties. *Hard-drawn steel spring wire* (A227-47) is a 0.45 to 0.75% carbon steel, cold drawn to produce the desired physicals. *Oil-tempered steel spring wire* (A229-41) is a 0.55 to 0.75% carbon steel, hardened and tempered to produce the desired physicals. *Chromium-nickel corrosion-resisting steel spring wire* (A313-47) is an 18-8 stainless steel, cold drawn to produce the desired physicals. It will operate up to 350 F without noticeable loss in physical properties. Even at 600 F, the loss is small enough to permit its use for thermostat, stove, and other applications. *Chromium-vanadium* steel spring wire (A231-41) and valve spring quality wire (A232-47) are annealed and cold drawn or oil tempered to produce the desired physical properties. They possess high fatigue-resisting properties, especially at moderately elevated temperatures.

Wire for Rope. Table 9 gives the strength of uncoated and galvanized wire used in the manufacture of wire rope. These are part of the Federal specifications for wire rope.

Table 9. Ultimate Tensile Strength of Main Wires for Rope

(Data from Federal Standard Stock Catalog)

Wire Material and Diam, in.	Minimum Tensile Strength, 1000 psi	
	Uncoated	Galvanized
Iron	70	55
Annealed steel	...	60
Highway-guard steel	...	90

.101–.140	225	202.5
.141–.190	218	196.2
Phosphor bronze	90	.....

The strengths of various wire rope constructions are given in Article 4 of this section. Zinc-coated steel wire strand is also covered by ASTM A122-41 and A218-41.

COPPER WIRE specifications for engineering applications cover wire intended for use in electrical conductors. Strength requirements of hard-drawn copper wire (ASTM B1-47), medium-hard copper wire (B2-47), and soft or annealed copper wire (B3-45) are given in Table 10. Other ASTM specifications cover tinned soft or annealed copper wire for electrical purposes (B33-46), as well as copper trolley wire and various types of stranded conductors. Copper alloy wires are also covered by ASTM specifications, including hard-drawn copper alloy wires for electrical conductors (B105-47), beryllium-copper alloy wire (B197-47T), brass wire (B134-48), and bronze trolley wire. Availability of various copper alloys in wire form is indicated in Table 4 on pp. 4-30 to 4-37.

4. WIRE ROPE *

Wire rope is a machine element designed primarily to transmit motion in any plane, turn corners readily and easily, and operate in restricted space. Because of its high weight-strength ratio it has almost entirely superseded chain or hemp rope for hauling, hoisting, or supporting loads. The multiple-wire construction insures the maintenance of adequate safety factors and provides the means for estimating its condition during

---

* In 10 in. for wire diameter 0.2294 in. and above; in 60 in. for wire diameter 0.2043 in. and below.

† Often employed for communication lines; not in the American Wire Gage (B & S) series.

operation. Like any other intricate equipment, however, it must be handled and maintained with care in order to provide safe and economical service.

Wire rope is made in four standard grades which, in ascending order of strength, are: iron, mild plow steel, plow steel, and improved plow steel. The most common constructions are made of six strands laid around a fiber or metallic core. The metallic core may be a wire strand or an independent wire rope. Numerous types and sizes of wire rope are engineered for specific purposes, the number, size, and arrangement of wires in each strand providing the different properties. For example, a rope with six strands of seven wires each is less flexible than one with 37 wires to the strand, but the 6 by 7 rope is more resistant to wear and abrasion.

Selection of the proper size, grade, and construction should be done by thorough consideration of all pertinent data, including all loads; acceleration; deceleration; rope speed; rope attachments; the number, size, and arrangement of all sheaves and drums; conditions causing corrosion and abrasion; length of rope used; economical rope life; and protection of life and property. The following information, therefore, is briefed in order to help in evaluating the foregoing factors.

BREAKING STRENGTH OF WIRE ROPE. The various manufacturers have adopted standard figures for the strength of all sizes and qualities of wire rope. Formerly it was the custom to test the individual wires and to consider their combined strength as the strength of the rope as a whole. These strengths were greater than the actual strength obtained by breaking the finished rope. The figures given in Tables 13 to 28 represent actual breaks of the various ropes and range from 95 to 80% or less of the combined strength of the single wires, depending on the construction.

LAY OF WIRE ROPE. Regular lay of wire rope comprises wires in the strands laid to the left, the strands being laid to the right. This is known as right-lay rope. If the wires are laid to the right and strands to the left, it is known as left-lay rope. Standard rope is made regular lay, right lay. In Lang lay rope, the wires in the strands and the strands themselves are laid in the rope in the same direction, either right or left.

Lang lay rope is somewhat more flexible than regular lay rope and, as the wires are laid more axially in the rope, longer surfaces are exposed to wear and the endurance thereby is increased. Owing to improvements in its manufacture, Lang lay rope now is used extensively in the United States. Standard Lang lay rope requires more care in handling and use than regular lay rope. By preforming, its tendency to untwist has been greatly reduced; also, the unlaying of the strands when the rope is cut has been eliminated. Improved handling, flexibility, drum winding, and ultimate rope life are also obtainable.

SHEAVES AND DRUMS. Drums and sheaves of the largest practicable diameter are recommended in all wire rope installations. See Table 11. If possible, drums should be lagged, and, where feasible, a grooved drum on hoists is more desirable than a flat drum. The grooves should give ample clearance between successive windings; thus a drum for 3/4-in. rope should have the grooves at least 7/8 in. apart on centers. The grooves should be made smooth in order not to cut the rope, and they should be of slightly larger radius than the rope in order to avoid wedging or pinching it. See Table 12. Overwinding, that is, the winding of the rope in more than one layer, is to be avoided, if possible, by making the drum large enough to take all the rope in a single layer. Overwinding will rapidly destroy the rope, and the extra cost of the larger drum will be more than compensated by the greater life of the rope. The best possible alignment of sheaves and drums should be made to avoid undue wear on the sides of the sheaves and the rope. In general, the lead sheaves over which the rope runs from the drum should be aligned with the center of the drum or, if the drum is not entirely filled, with the center of the portion on which the rope is wound. The distance between the drum and lead sheave should be such as to cause an angle not exceeding 1° 30′ between the line from the center of the sheave to the center of the drum, and the line from the center of the sheave to the outer side of the drum. When the sheaves become worn, they should be replaced or the grooves turned before they are used with a new wire rope, otherwise the rope will not work properly. When changing an old rope for a new one, the sheaves should be examined, and, if scored or cut from the old rope, they should be turned, relined or renewed, so that the new rope will not receive undue wear. For many purposes, particularly mine service, the grooves can advantageously be lined with well-seasoned, hardwood blocks set on end, which can be renewed when worn. Large sheaves, running at high velocity, should be lined with

Table 11. Recommended Minimum Diameter of Sheaves and Drums for Wire Rope

(Federal Specification RR-R-571a)

No. of Strands	Wires per Strand	Minimum Sheave or Drum Diameter	
5	19	45	
6	7	72	× the
6	19	45	nominal
6	25	45	diameter
6	29	30	of the
6	37	27	wire rope
6	42	24	
8	19	31	

Average recommended diameter is about 50% greater than the minimum.

Table 12. Requirements for Groove Diameter

(Federal Specification RR-R-571a)

Nominal Rope Diameter, in.	Amount Groove Diameter Should Be Larger than Nominal Rope Diameter: For Minimum Conditions	Amount Groove Diameter Should Be Larger than Nominal Rope Diameter: For New or Regrooved Sheaves
1/4 to 5/16	1/64	1/32
3/8 to 3/4	1/32	1/16
13/16 to 1 1/8	3/64	3/32
1 3/16 to 1 1/2	1/16	1/8
1 9/16 to 2 1/4	3/32	3/16
2 5/16 and over	1/8	1/4

leather set on end, or with rubber. This is the usual practice for power transmission between distant points, where the rope frequently runs at a velocity of 4000 ft per min.

REVERSE BENDING. Reverse bending, that is, bending the wire rope first in one direction over sheaves and then in the opposite direction, is to be avoided wherever possible. This practice will wear out a rope more quickly than any other known method. A little care in design usually will eliminate all situations that call for reverse bending, and it is even desirable to change existing constructions if necessary to remove this condition. The expense of rope renewals will more than equal the cost of change, as a rule.

HANDLING WIRE ROPE. Wire rope must not be coiled or uncoiled like hemp rope. When received in a coil, it should be rolled on the ground like a hoop and straightened out before being put on the sheaves. If on a reel, it should be mounted on a spindle or a flat turntable and properly unwound. Kinking or untwisting must be avoided.

PROTECTION AND LUBRICATION OF WIRE ROPE. Wire rope should be protected by a suitable lubricant, both externally and internally, to prevent rust and to keep it pliable. The lubricant should be suited to the conditions under which the rope is used. It should not contain acids or other corrosive agents and should readily penetrate the strands. It should be self spreading, adhesive, and water repelling. The higher the speed of the rope, the lower should be the viscosity of the lubricant. For stationary ropes for low-speed work, as on shovels, cranes, or derricks, a heavy petroleum oil or grease, viscosity approximately 1000 sec at 210 F, applied hot, is advised. For heavy haulage, as slope and logging ropes, a lubricant of viscosity of 500 to 800 sec at 210 F should be used. For high-speed hoisting, as in mine hoists, a lubricant of viscosity of 400 to 500 sec at 100 F is recommended, with automatic lubrication. In all cases, the viscosity should be such that the lubricant will cover the rope, penetrate thoroughly, withstand pressure, but yet not be so thin as to run off the rope. Crude oils should not be used. New lubricants only should be applied. Lubricants should be applied hot, as the penetration thereby is increased, and when cooled the lubricant exists as a plastic filler to lubricate the wires and to exclude moisture. The lubricant is best applied by passing the rope through a bath of heated oil. Placing a drum of heated oil over the rope and allowing the oil to flow on the rope is wasteful of oil. When hand lubrication is necessary, a piece of sheepskin with the wool coat on the inside is recommended as a wiper, the wool being saturated with oil, and held around the rope as it passes through the wiper. While in storage, wire rope should be kept dry and protected from the weather, acid, and acid fumes. When a used rope is stored, it should be thoroughly cleaned before oiling and then treated as a new rope. For special cases, the manufacturers of wire rope should be consulted as to the type and method of lubrication.

EXPOSURE TO HEAT. Where wire rope is exposed to intense heat, as in foundry or steel mill service, a wire core is often substituted for the fiber core.

GALVANIZED WIRE ROPE is used for "standing" service, where no bending is required, as guys, ship's rigging, towing and mooring lines, etc. It is not adapted to hoisting service, as the galvanized coating is abraded and worn away by the sheaves, thus promoting corrosion. The more commonly used types of galvanized wire rope are described below.

Galvanized standing and guy rope is made in all grades. Iron guy rope, being soft, is more readily subject to damage than the harder, high-strength, steel grades and is not recommended. The higher grades have an elastic limit which is a greater percentage of their ultimate strength and hence are more adaptable to designs where the elastic limit is the design criterion. Galvanized rope in the higher-strength grade has often been used for guying radio towers, stacks, and derricks.

Guy rope is made with 6 strands of 7 or 19 wires per strand. A steel core is generally preferred, owing to the higher strength and decreased stretch which it affords. Galvanized iron rigging and guy rope (6 by 7 sizes) are listed in Table 13. Steel rope of 6 by 7 sizes

Table 13. Standard 6 by 7 Galvanized Iron Rigging and Guy Rope

1 3/8	2.93	74.1	64.5				

* For these ropes with steel cores, add 7 1/2% to the above strengths. For these ropes when galvanized, deduct 10% from the above strengths.

Standard 6 by 7 wire rope with fiber core (Table 14) is made of large wires and is the least flexible of any standard rope. Mild plow-steel rope is particularly adapted to mine haulage work, including tail rope and endless haulage systems, gravity hoists, and coal and ore dock haulage, roads, operating small grip cars, etc. The sizes 3/8 to 5/8 in., inclusive, are used for sand lines in oil wells, and from 5/8 to 1 in. for oil-well drilling. In general, it can be used for severe service and where minimum flexibility is required. The plow-steel rope is advised for situations similar to those for which the mild plow-steel ropes are used but where it is necessary to secure increased strength without altering the working conditions. The wires are harder and capable of standing greater wear than any of the foregoing ropes. Improved plow-steel rope is the strongest and stiffest of all and is used for work demanding the greatest strength and lightest rope possible. Sheaves for this rope should, if possible, be somewhat larger than for other grades.

Standard 6 by 19 wire rope with fiber core (Table 15) is more flexible than the 6 by 7 rope, inasmuch as the wires are smaller for the same size rope. It will not stand as much abrasion as transmission rope. The fiber-center rope is very pliable and will wind on moderate-size drums and sheaves without injury. If possible, drums and sheaves should be larger than shown in Table 11. The mild plow-steel, plow-steel, and improved plow-steel ropes are adapted to mine hoisting, logging, quarrying, elevators, derricks, hay presses, dredges, cableways, inclined planes, coal hoists, conveyors, ballast unloaders, skip hoists, and similar applications.

Standard 8 by 19 wire rope with fiber core (Table 16) has even greater flexibility, permitting its use on smaller sheaves and drums, such as usually are found on derricks. It is not advisable to use it where there is much overwinding, as it will flatten much more quickly than the 6 by 19 standard rope. Its uses are the same as those of standard 6 by 19 hoisting rope.

Standard 6 by 37 wire rope with fiber core (Table 17) is extremely flexible and is especially adapted to high-speed service on cranes or where sheaves are small. It will not stand so much abrasion as the 6 by 19 rope, but it is particularly efficient, as over 50% of the wires are in the inner layers and are protected from abrasion. The improved plow-steel rope is largely used on dredges for both main and spud ropes as well as hoist and boom ropes on large power shovels and draglines.

FLATTENED STRAND ROPE has triangular or sector-shaped strands which allow greater metallic area than is possible with round strand ropes. The shape of the strands gives more wearing surface and increased resistance to crushing. However, this construction is not so flexible or so fatigue resistant as round strand rope of the same general classification.

Flattened strand ropes are made in three styles, B and G for hoisting and D for haulage (see Tables 18, 19, and 20).

NONROTATING ROPE (Table 21) is fabricated by laying 18 7-wire strands around a fiber core in two concentric layers, the inside and outside layers being laid in opposite directions. The tendency for twisting between the inside and outside layers is therefore opposite, which balances the rope and establishes the nonrotating characteristic.

3/4	0.97	21.8	19.0	1 5/8	4.57	98.4	85.6
7/8	1.32	29.5	25.7	1 3/4	5.30	114.0	98.8

* For these ropes when galvanized, deduct 10% from the above strengths.

Nonrotating rope is used for hoisting on equipment where rotation is to be restricted. However, such ropes have less strength than similar-size ropes of other construction.

ELEVATOR ROPE. Table 22 gives the characteristics of standard 6 by 19 and 8 by 19 elevator rope.

MARLINE-CLAD ROPE is a round strand rope, each strand being given an external serving of tarred marline (see Table 23). It is particularly adapted for ship rigging, cargo hoists, power transmission, grain shovels, etc.

* For these ropes with steel cores, add 7 1/2% to the above strengths. For these ropes when galvanized, deduct 10% from the above strengths.

FLAT ROPE. Flat rope consists of a number of "flat-rope" strands, laid alternately right and left, then placed side by side and sewed together with soft steel wire, to form a flat rope of the desired width and thickness. The soft sewing wires wear much quicker than the rope wire and have to be replaced from time to time, at which time worn strands can also be renewed. Flat rope is used principally for hoisting heavy loads out of deep shafts. It requires a reel but little larger than the width of the rope, whereas round rope necessitates the use of a large drum. Its use is recommended where saving of machinery space is an object. It does not twist or spin in the shaft. It is also used for operating spouts on coal and ore docks, for raising and lowering emergency gates on canals, and for similar machinery. For details of methods of fastening it to drums, the manufacturers should be consulted. Drums and sheaves should be as large as possible. A rule for the diameter of the drum is $D = ct$, where D is diameter of drum at bottom in inches, t = thickness of rope in inches, and c = 100 for drums and 160 for sheaves. Sheaves should be crowned at the center and have deep flanges to guide the rope. (See Table 24.)

RUNNING ROPES AND HAWSERS are made of 6 12-, 24-, or 37-wire strands. (See Tables 25, 26, and 27.) The 6 x 12 and 6 x 24 constructions have fiber core in each strand for increased flexibility; the 6 x 37 hawsers have all steel strands. They are lighter than hemp hawsers of equal strength and are flexible enough to work around the same bitts as hemp rope of equivalent strength. The following is a comparison of hawsers of equal strength:

AIRCRAFT CORD AND STRAND. Special types of wire rope have been developed for aircraft use, as multiple-wire strand and as multiple-strand cord (Tables 28 and 29). They are furnished in tinned or galvanized carbon steel or in stainless steel and meet Army-Navy specifications. Aircraft cord is also available with an aluminum alloy tube swaged over the outside, providing a smooth surface, less stretch, and a coefficient of thermal expansion close to that of the aluminum alloy airframe. Such clad cord can be used only on straight runs. It is covered by U. S. Patent 2,308,669.

WIRE ROPE FITTINGS. (See also page 26-05.) **Splices.** Two types of splices are used with wire rope—the long or endless, and the loop or thimble splice. The long splice is used to attach one rope to another or to make a rope endless by interlocking the strands. Ropes of similar construction can be so spliced, but a right lay rope cannot be spliced into a left lay rope. In making a splice, a certain amount of rope is used up so additional length must be allowed for it.

The loop splice is made by forming a loop in the end of the rope and then interlocking the strands. The loop often contains a thimble or other fitting.

The endless splice is made in the same manner as the end-to-end splice.

The thimble splice is the forming of a loop in the end of a rope and then interlocking the strands, the loop usually containing a thimble or other fitting (Fig. 2).

Shackles are used to connect ropes whose ends are equipped with thimbles, sockets, turnbuckles, etc. (See Fig. 2.)

Clips are fastenings usually used to form a thimble loop where the use of the rope is temporary. The U-bolt of the clip should rest on the short end of the rope so that the flat bears on the tension side of the loop. Otherwise the rope will be injured by the clip

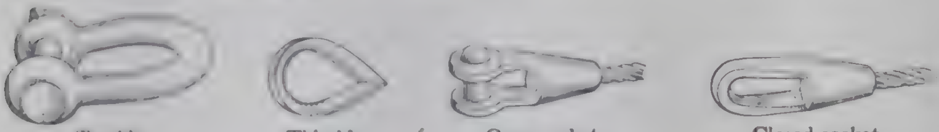
putting a crimp in the tension side. Not less than 2, and preferably 4 or 6, clips should be used, especially on the larger diameters of rope.



Shackle
Thimble
Open socket
Closed socket

FIG. 2. Wire rope fastenings.

Clamps are temporary fastenings, usually used to form loops without thimbles. From 2 to 6 clamps should be used for each end fastening, and alternate clips and clamps are preferable.

Turnbuckles are necessary where slack in rope is to be taken up or a uniform tension maintained. The turnbuckles should always be equal in strength to that of the rope used with them. Where a greater take-up is required than that given in the table, two or more turnbuckles should be used. Turnbuckles are usually made with the styles of ends shown in Fig. 3.

Sockets are the strongest type of rope fastening. (See Fig. 2.) Bridge sockets of both open and closed type are also made for bridge cables and locked tramway and cableway strand. Sockets develop the full strength of the rope and are stronger than any rope that may be inserted in them.

Swaged Fittings. Where a light, compact, and highly efficient connection is desired, a swaged or compressed fitting may be used. When properly designed and attached, they develop the full strength of the cord or rope and thus have found many industrial applications. Swaged fittings for all types of aircraft control cords have superseded former methods of making attachments. The adaptability of this method has allowed the use of special fittings, such as shown in Fig. 4, which previously were unavailable.

5. ROPE

MANILA ROPE. Table 30 gives the weight and strength of manila rope in the sizes available. These figures correspond to the specifications of the U. S. Bureau of Standards.

STRESS DUE TO LENGTH OF VERTICAL ROPE. In a very long rope, the weight of the rope itself adds a considerable amount to the stress in the rope and decreases the

Table 30. Weight and Strength of Three-strand Manila Rope *

* Four-strand rope weighs about 5% more than 3-strand rope; the tensile strength is about the same as that of 3-strand rope.

load that the rope can safely carry. The weight of the rope, as a whole, can be diminished by making it up of a series of ropes of constantly decreasing diameters, the smallest rope being at the lower end. Table 31 shows the length of rope, hanging vertical, that will develop the maximum stress in the rope. The figures are based on the values of Table 30.

MANILA ROPE FOR HOISTING OR TRANSMISSION. Rope for hoisting or power transmission is subject to severe usage. Ordinary rope chafes and grinds to powder in the center, although the exterior may look little worn. In bending a rope over a sheave, the strands and the yarns of these strands slide a small distance upon each other, causing friction, and wearing the rope internally. This condition can be alleviated by proper lubrication of the rope. The selection of the lubricant depends on the use of the rope. For indoor use, the lubricant should be one that will not dry out the rope nor rub off easily. For outdoor use, a graphite lubricant of fine flake graphite should be worked into the yarns while the rope is being made, so that each fiber is impregnated.

The amount of work that the rope will do varies greatly. It depends not only on the quality of the fiber and the method of laying up the rope but also on weather when the rope is used, the blocks or sheaves over which it is run, and the strain in proportion to the strain put upon the rope. The principal wear comes in practice from defective or badly set sheaves, excess of load, and exposure to storms.

Loads put on the rope should not exceed those given in the tables, for the most economical wear. Indications of excessive load will be the twist coming out of the rope, or one of the strands slipping out of its proper position. A certain amount of twist comes out in use in the first day or two, but the rope then should remain substantially the same. If it does not, the load is too great for the durability of the rope. Wear of the rope on the outside, while it is good on the inside, indicates chafing in running over pulleys or sheaves. Very small blocks will increase the sliding of the strands and threads and result in a more rapid internal wear. For further information on rope for power transmission, see Article 26, Section 15.

TECHNICAL TERMS RELATING TO CORDAGE most frequently used are:

Yarn. Fibers twisted together. Yarns are laid up left-handed into *strands*.

Thread. Two or more *small yarns* twisted together.

String. The same as a thread but of a little larger *yarns*.

Strand. Two or more *large yarns* twisted together. Strands are laid up right-handed into rope.

Cord. Several threads twisted together.

Rope. Several *strands* twisted together.

Hawser. A rope of three *strands*. Hawsers are laid up left-handed into a cable.

Shroud laid. A rope of four *strands*.

Cable. Three hawsers twisted together.

A rope is:

Laid by twisting strands together in making the rope.

Spliced by joining to another rope by interweaving the strands.

Whipped by winding a string around the end to prevent untwisting.

Served when covered by winding a yarn continuously and tightly around it.

Parceled by wrapping with canvas.

Seized when two parts are bound together by yarn, thread, or string.

Payed when painted, tarred, or greased to resist wetting.

Hauled when pulled on.

Taut when drawn tight or strained.

SPLICING OF ROPE. The splice in a transmission rope is the weakest part of the rope and the first part to fail when the rope is worn out. If the rope is larger at the splice, the projecting part will wear on the pulleys and the rope will fail from the cutting off of the strands.

EFFICIENCY OF SPLICES AND KNOTS as a percentage of the full strength of the rope, and the factor of safety when used with the stresses given below, are as follows:

Kind of Knot	Efficiency, %	Factor of Safety
Eye splice over an iron thimble	90	6.3
Short splice in the rope	80	5.6
Timber hitch, round turn, half-hitch	65	4.5
Bowline slip knot, clove hitch	60	4.2
Square knot, weaver's knot, sheet bend	50	3.5
Flemish loop, overhand knot	45	3.1
Full strength of dry rope, average of four tests	100	7.0

Diameter of rope, in.	1	1 1/8	1 1/4	1 3/8	1 1/2	1 5/8	1 3/4
Working stress, lb	1000	1250	1500	1900	2200	2600	3000

6. CHAIN

CLASSES OF CHAIN. Two classes of chain are covered by ASTM A56-39; *crane chain* and *proof coil*. Strength, weight, and dimensions of these are given in Tables 32 and 33.

Crane chain is intended for slings, cranes, steam shovels, and marine uses where an all-iron chain is desired. It is made from all pig-puddled or processed wrought iron, free from any admixture of iron scrap or steel, and lap fire welded. Composition includes not more than 0.06% manganese.

Proof coil is intended for railroad cars, construction, and forestry work. It is made from open-hearth steel and may be either fire welded or electrically welded. Composition includes not more than 0.05% phosphorus and 0.05% sulfur.

Physical Properties and Tests. Chain subjected to the proof test load, Table 32, should show no defects. The break test load is applied to a test specimen not less than 2 ft in length cut from the finished chain. Elongation in 12 to 18 in. to the nearest link should be not less than 15%.

Standard weights and dimensions are given in Table 33. Permissible variation for length and weight of chain is ±4%. Length is determined by measuring to the inside of the end links, after the proof test, with a load not exceeding 10% of the proof test load to take up slack. Diameter of the weld should not exceed 25% of the bar diameter unless otherwise specified.

CAUSES OF CHAIN FAILURE. 1. Brittle failure is caused by cold-working of the metal surface. The metal fractures with no elongation, or with less elongation than in the ordinary tensile failure mentioned under (6). This type of fracture usually is caused by a brittle surface skin developed on the metal by impacts received in service. Brittle failures show a more or less crystalline fracture, especially where the brittleness is present in an extreme degree. In service, fractures caused by cold-working the surface occur most frequently in the sides or near the shoulder of the link. Where the surface hardening is extreme, the fracture extends directly across the metal of the link in an approximately plane surface. Brittle failures usually are found in chain which has failed under the impact of suddenly applied loads.

2. Failure in the weld covers any failure involving partial or total separation of the welded surfaces. In old chain, welded surfaces often show signs of progressive deterioration and oxidation.

3. Failure due to repeated severe bending or deformation of the links is similar to that produced in a bar by repeated bending back and forth. This is common in long link chains, as conveyor chains. The fractured surface usually is crystalline, both in wrought iron and steel.

4. **Fatigue failure** is produced by many repetitions of stress exceeding the fatigue limit of the metal. In fatigue tests on chain links, the fracture usually occurs at about the quarter point of the link. The fracture extends directly across the side of the link. Fatigue failure occurs in chain in machines or appliances used for repeated liftings of a given load, but it is not common in crane chains and sling chains. There is no elongation of the metal. The fractured surface is usually plane and crystalline.

5. **Brittle failure caused by defects in the metal** are comparatively rare. The proof test by the manufacturer detects brittleness from this cause, and the links are removed. Brittle fractures, due to overheating during welding, are rare.

6. **Ordinary tensile failure,** accompanied by full elongation of the metal of the links, usually occurs in new chain of good quality when the chain is required to carry a load greater than its ultimate tensile strength. The metal of the links elongates greatly and the chain "pulls stiff" before final failure. The fracture usually occurs in the sides of the links near the welded end. The metal "necks down" and pulls apart as in an ordinary tension test. The fractured surfaces are generally silky in steel, or fibrous in wrought iron.

USE OF CHAIN. The diameter of a sheave or winding drum used with a short link chain should be from 25 to 30 times the diameter of the stock used for the link, to minimize the bending stresses in the chain as it passes over the sheave or drum. Where the application requires a longer link, the chain manufacturer should be consulted as to the proper size of drum or sheave. Sheaves and drums used should be grooved to receive the chain. These grooves should be of such shape and size as to allow the chain to work smoothly without twisting. Chain should not be wound on sheaves, shafts, or drums without proper grooves.

Splicing of Broken Chain. A dangerous practice, which should be prohibited, is that of splicing a broken chain by inserting a bolt between two links, with the head of the bolt and the nut sustaining the load, or of passing one link through another and inserting a bolt or nail to hold it.

Kinked, Knotted, or Twisted Chain. A lift never should be made with a kink, knot, or twist in the chain. The chain should be perfectly straight. Twisting and dragging chain over pipe and other materials injures the chain.

Safe Loads. Some plants stamp on a metal tag attached to each chain the safe vertical load which may be lifted with that chain. A better way is to stamp the safe load or a reference number for the chain load on the ring or hook. Stamp marks should not be placed on chain links as they may form points of weakness in the surface of the links when they are in cold-worked condition, which may start a crack. Some chain users weld to the ring or connecting link of the chain a flat link on which the safe load or number may be marked. This flat link does not form a part of the chain to which the load is applied. A greater load can be lifted safely with a given size of chain or sling when the chain or all the legs of the sling are in a vertical position.

LUBRICATION. To lessen wear of the chain links when wound on a drum and passed over sheaves, they should be lubricated at frequent and regular intervals with grease or heavy oil mixed with graphite. When lubricating, the chain should be slack and the oil brushed well in between the ends of the links. Grease and oil should not be used in places such as foundries where grit and sand particles are present, resulting in severe abrasive action. Sling chains should not be lubricated, as the lubricant would be transferred to the bodies of men handling the chain, introducing a hazard. The lubricant may also increase the slipping hazard.

METHOD OF EXAMINATION. It is important to examine all hoisting chains at frequent and regular intervals. The examination should include inspection of the links for stretch, wear, gouge marks, open welds, and especially a careful inspection of the surface to ascertain the need of annealing or normalizing, as indicated by the peened, hammered, or polished surface of the links. The examination should be made by a person who is conversant with the defects and flaws liable to be found and who has the knowledge and authority to decide when the chain should be removed from service for repair, annealing, normalizing, or replacement.

BENT HOOKS. Hooks which have become bent owing to overloads, should not be straightened and put back into service. Once a hook is bent, the stress in the metal tends to weaken it so that its strength afterward is doubtful.

MECHANISM

1. DEFINITIONS

A MACHINE is a combination of resistant bodies so arranged as to compel the forces of nature to produce work with determinate motions.

A MECHANISM is a combination of resistant bodies so arranged that the motion of one compels the motion of the others, according to a law depending on the nature of the combination. A machine modifies energy and a mechanism modifies motion.

A STRUCTURE is a combination of resistant bodies capable of transmitting forces or carrying loads but having no relative motion between parts.

THE FRAME of a machine is a structure which supports the moving parts and regulates the path, or kind of motion, of some of the parts.

THE DRIVER is that piece of a mechanism which causes motion.

THE FOLLOWER is that piece of a mechanism whose motion is effected.

A PAIR OF ELEMENTS is the geometrical form used to join two parts of a machine so as to obtain definite relative motion between the parts.

A LINK is a rigid piece or a nonelastic substance which serves to transmit force from one piece to another or to cause or control motion.

A LINKAGE consists of a number of pairs of elements connected by links.

A CRANK is a body rotating or oscillating about an axis. When two cranks on the same axis are rigidly connected to each other the combination is called *a lever*.

A CONNECTING ROD is the body joining the moving ends of the two cranks of a four-bar mechanism.

EFFICIENCY OF A MACHINE is the ratio of the useful work performed to the total work received. The efficiency is usually expressed as a percentage but used as a decimal quantity. The limit to the efficiency of a machine is unity, denoting the efficiency of a perfect machine in which no work is lost.

2. LINKAGES

A FOUR-BAR LINKAGE (Fig. 1) consists of two cranks, 2 and 4, a stationary piece, 1, or frame, called the line of centers and the connecting rod, 3. In general, any mechanism can be analyzed as a four-bar linkage or a combination of such linkages. The angular speeds of the two cranks of a four-bar linkage are inversely proportional to the lengths of the perpendiculars or any two parallel lines drawn from the fixed centers to the center line of the connecting rod. In Fig. 1

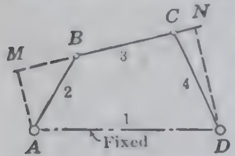

Fig. 1. Four-bar linkage.

$$\frac{\text{Angular velocity of crank 2}}{\text{Angular velocity of crank 4}} = \frac{DN}{AM} \qquad (1)$$

CRANK AND ROCKER (Fig. 2). In this combination the link AD is fixed, the crank AB revolves in a complete circle about its fixed axis A and imparts an oscillating motion to the rocker CD about the fixed axis D through the connecting rod BC. In order for this linkage to operate, the following conditions must exist:

1. $AB + BC + DC > AD$
2. $AB + AD + DC > BC$
3. $AB + BC - DC < AD$
4. $BC - AB + DC > AD$

Either AB or DC may be the driving crank. If AB drives, the mechanism always will operate. If DC drives, it will not operate unless a flywheel or other aid carries the crank over the dead-center points.

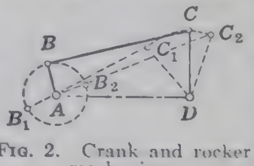

Fig. 2. Crank and rocker mechanism.

DRAG LINK (Fig. 3). If the link AB in Fig. 2 is fixed and the proportions of the links are nearly the same the links BC and AD will rotate about the fixed points B and A, respectively, becoming cranks, and CD becomes the connecting rod. This mechanism

(Fig. 3) is called a drag link. In order for the cranks to make complete revolutions without any dead centers the following conditions must exist:

1. $CD > AB + AD - BC$ 2. $CD < AD + BC - AB$

PARALLEL CRANK FOUR-BAR LINKAGE. If in Fig. 1 the cranks AB and DC are of equal length and the connecting rod BC is equal in length to the line of centers AD, the two cranks always will turn at the same angular speed.

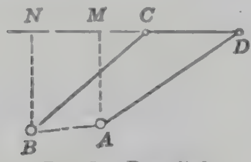

FIG. 3. Drag link.

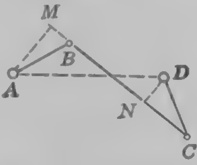

FIG. 4. Nonparallel equal crank linkage.

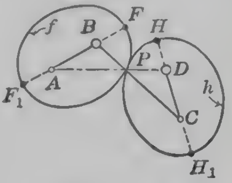

FIG. 5. Elliptic gears. Compare with Fig. 4.

NONPARALLEL EQUAL CRANK LINKAGE (Fig. 4). If the cranks AB and DC are made of equal length, but point in opposite directions from their centers, motion imparted to one crank will cause the other to rotate in the opposite direction. If crank AB is given a uniform angular motion, crank DC will have a varying angular speed. The opposite sense of rotation may be received by providing some means of causing the cranks to pass the dead centers in the proper sense. This may be accomplished by some device placed at the instantaneous axis of the connecting rod when in these positions. Linkages of this type may be replaced by gears (Fig. 5) which are cut on the circumferences of ellipses f and h whose foci are A and B and D and C, respectively, and whose major axes are AD and BC. The intersection of links BC and AD at all positions of the linkage is a point on the circumference of the two ellipses and, therefore, is the point of tangency.

SLOW-MOTION LINKWORK. Figure 6 shows a four-bar linkage proportioned so as to produce slow motion of the crank DC. As the crank AB is rotated clockwise it imparts motion to crank DC, whose angular velocity decreases to zero when the crank AB reaches its dead-center position with the connecting rod BC in line with the crank.

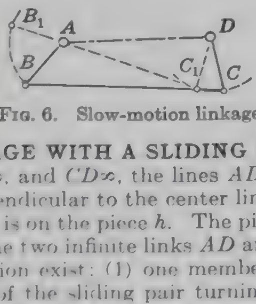

FIG. 6. Slow-motion linkage.

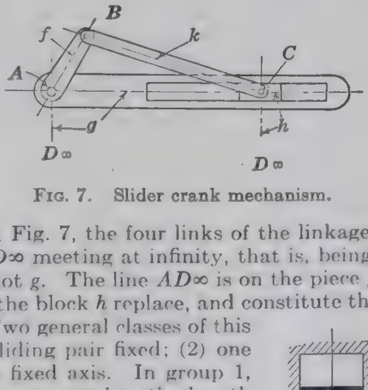

FIG. 7. Slider crank mechanism.

LINKAGE WITH A SLIDING PAIR. In Fig. 7, the four links of the linkage are AB, BC, $AD\infty$, and $CD\infty$, the lines $AD\infty$ and $CD\infty$ meeting at infinity, that is, being parallel, and perpendicular to the center line of the slot g. The line $AD\infty$ is on the piece g and the line $CD\infty$ is on the piece h. The piece g and the block h replace, and constitute the equivalent of, the two infinite links AD and CD. Two general classes of this combination exist: (1) one member of the sliding pair fixed; (2) one member of the sliding pair turning about a fixed axis. In group 1, the connecting rod BC can be longer, shorter, or equal to the length of the crank AB. In group 2, the crank can be longer, shorter, or equal to the line of centers.

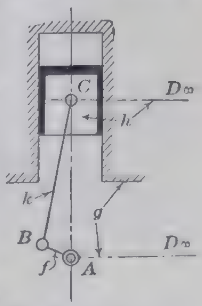

FIG. 8. Sliding-block linkage.

Sliding-block Linkage. Figure 8 is a line drawing, notated as in Fig. 7, of the cylinder, piston, connecting rod, crank, and crankshaft of a gasoline engine. This linkage is commonly called a slider-crank mechanism. The cylinder g, though not absolutely fixed to the earth, is fixed to the frame and is considered as the fixed piece of the four-bar linkage. The crankshaft A turns in bearings rigidly attached to the cylinder. The line $AD\infty$ is the line of centers, f the finite crank, k the connecting rod, and the line $CD\infty$ the infinite crank. The piston h receives its energy from the exploding fuel and is the driving member. The same mechanism is used in steam engines and reciprocating pumps and compressors. In these machines the slider h, called the cross head, is connected rigidly to the piston by the piston rod. In the steam engine the cross head is the driver, in the pump and compressor the crank f is the driver. When the slider C is the driver, means must be provided to carry the crank over the dead-center positions, as by a flywheel or by two such linkages, the cranks of which are keyed to the same shaft and set at right angles to each other. The displacement of the piston C from the head end dead center is

$$X = R(1 - \cos\theta) + L\left(1 - \sqrt{1 - \left(\frac{R}{L}\right)^2 \sin^2\theta}\right) \tag{2}$$

where X = displacement, inches; R = length of crank AB, inches; L = length of connecting rod BC, inches; and θ = crank angle (angle CAB in Fig. 8), degrees. An approximately correct formula for the displacement is

$$X = R(1 - \cos\theta) + \frac{R^2 \sin^2\theta}{2L} \tag{3}$$

The position of the piston for various crank angles is given in Table 1. If the center line of motion of the reciprocating parts is not in the same plane as the center line of the

crankshaft but is at a perpendicular distance d away from it, the stroke is greater than $2R$, and the dead centers are not symmetrical. In this case the length of the stroke S is

$$S = \sqrt{(1 + R)^2 - d^2} - \sqrt{(1 - R)^2 - d^2} \tag{4}$$

The linear velocity of the piston in inches per second, V, is approximately

$$V = R\omega\left(\sin\theta + \frac{R}{2L}\sin 2\theta\right) \tag{5}$$

where ω = angular velocity of crank AB, radians per second. For velocities of piston at various crank angles and L/R ratios, see Table 1, p. 7-36.

The linear acceleration of the piston in inches per second per second, A, is approximately

$$A = R\omega^2\left(\cos\theta + \frac{R}{L}\cos 2\theta\right) \tag{6}$$

For acceleration factors at various crank angles and L/R ratios, see Table 2, p. 7-38.

Swinging-block Quick-return Mechanism. Figure 9 illustrates a case of the second class noted above wherein the line of centers BC is longer than the finite crank AB. The gear f, driven by the source of power, rotates about the fixed axis B. Attached to f is the pin whose axis is A. On this pin is the block g which slides in the slot in the swinging arm h. The arm h oscillates about the fixed axis C. The driving crank f, being a part of the gear, turns at a uniform angular speed. The ratio of the time of the working stroke to the time of the return stroke is equal to the ratio of the angles through which f turns during these respective motions.

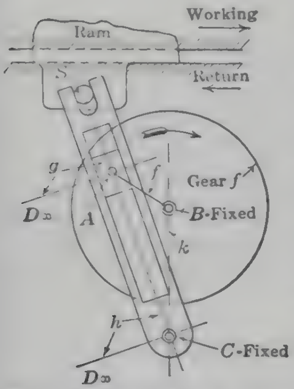

FIG. 9. Swinging-block quick-return mechanism.

Turning-block Linkage. Figure 10, a diagram of the Whitworth quick-return mechanism, illustrates another case of the second class noted above wherein the line of center AB is shorter than the finite crank BC. The action of this mechanism is similar to that of the swinging-block quick-return mechanism except that the crank g makes complete revolutions with variable angular speed but the arm h in Fig. 9 oscillates.

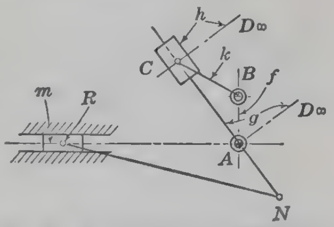

FIG. 10. Turning-block or Whitworth quick-return mechanism.

STRAIGHT-LINE MECHANISMS. If the connecting rod CB in Fig. 7 is made equal to the crank AB an isosceles sliding-block linkage results. If the connecting rod CB is extended to E making BE equal to CB (Fig. 11) the point E will travel in an exact straight line. This linkage may be modified by replacing the block h with a crank CD as in Fig. 12. This linkage is a form of the Scott Russell mechanism. The point E will trace an approximate straight line; the longer the crank CD is made, the less will be the deviation of E from the straight line yy. Figure 13 shows a form of the four-bar linkage as used in the Watt straight-line mechanism. The point P is so located as to cause it to trace a complex path yy, a portion of which is an approximate straight line. If the location of the fixed axes A and D, the position of the line yy along which the point P is to be guided, and the desired length of the stroke S are known, AB, BC, DC, and the location of the point P are found as follows:

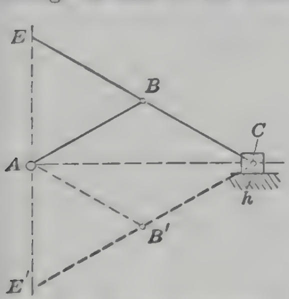

FIG. 11. Straight-line mechanism.

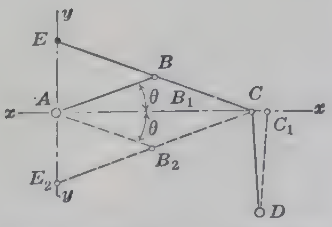

FIG. 12. Scott Russell straight-line mechanism.

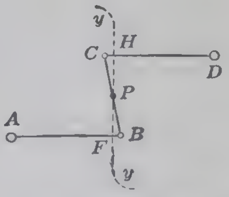

FIG. 13. Watt straight-line mechanism.

Draw AF and DH perpendicular to yy. Then

$$AB = AF + \frac{S^2}{16AF} \tag{7}$$

$$DC = DH + \frac{S^2}{16DH} \tag{8}$$

Join B and C; P will be the point where BC cuts yy.

THE PANTOGRAPH is a four-bar linkage with the opposite sides parallel and forming a parallelogram. In Fig. 14, the point E on link CD and the point P on BC extended will move parallel and similar to each other over any straight or curved path provided that E and P lie on the same straight line passing through the fixed point A. The displacement of P will equal the displacement of E times the ratio AP/AE.

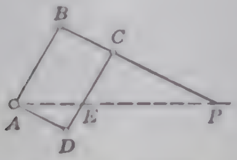

Fig. 14. Pantograph.

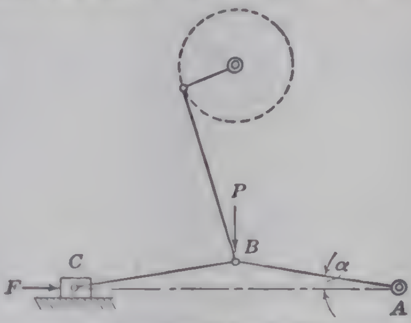

Fig. 15. Toggle mechanism.

THE TOGGLE MECHANISM (Fig. 15) is a combination of two four-bar mechanisms. When the block C approaches the end of its stroke, its velocity decreases, causing the block C to be capable of exerting a high force F with a low applied force P. If the linkage ABC is an isosceles sliding-block linkage,

$$\frac{P}{F} = \frac{2 \sin \alpha}{\cos \alpha} = 2 \tan \alpha \qquad (9)$$

THE GENEVA WHEEL (Fig. 16) offers a means of obtaining intermittent motion. In this particular case the starwheel A makes one-sixth of a revolution for one turn of the driving wheel B; however, velocity ratios other than 6 to 1 may be used. Motion is imparted to A by the pin b working in the radial slots b'. The circular portion c of the driver, coming in contact with the corresponding similar parts c', causes A to remain in position when the pin b is out of action. The wheel B is cut away as shown to provide clearance for A in its motion. In laying out the mechanism the angle β is made equal to 360 degrees divided by the number of slots required. The angle θ is drawn so that its side ab is perpendicular to the center line of the slot bd. If another pin is placed opposite b on wheel B as shown by dotted lines and proper clearance is allowed, wheel A would move one-sixth turn each half turn of B. If one of the slots on A, say b', is closed, wheel B can rotate only a little over 5 $^1/_2$ revolutions in either direction before pin b strikes the closed slot. This variation of the mechanism is called the *Geneva stop*.

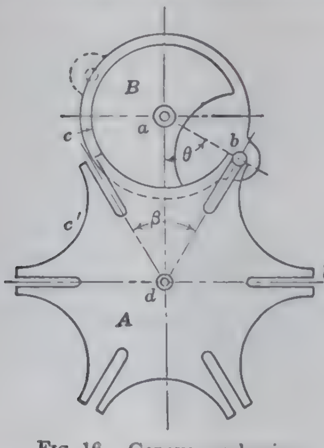

Fig. 16. Geneva mechanism.

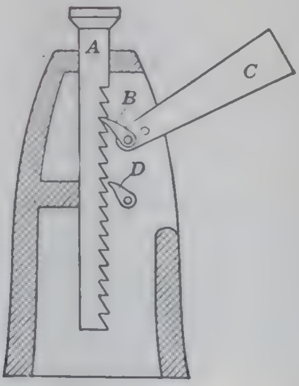

Fig. 17. Ratchet mechanism.

RATCHET MECHANISMS are used for obtaining intermittent rectilinear or rotary motion from another member which usually moves with reciprocating or oscillating motion. Figure 17 shows a ratchet mechanism used in a lifting jack. The *pawl, detent, click*, or *catch* B engages with the teeth on A, and by forcing the handle C downward, A is raised. The pawl D prevents A from moving downward when pawl B engages another tooth on A.

Figure 18 illustrates a ratchet mechanism where rotary motion is imparted to the wheel *A* by the movement of the arm *C* causing pawl *B*, in mesh with a tooth *b* on *A*, to rotate *A* about the axis *a*. Wheel *A* may be prevented from moving backward on the return of the pawl *B* by using a fixed pawl similar to *B*, turning on a fixed pin. Figure 19 shows a retaining pawl which prevents rotation of the wheel *A* in either direction.

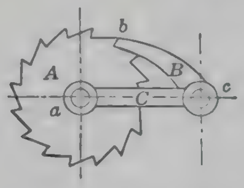

Fig. 18. Ratchet wheel.

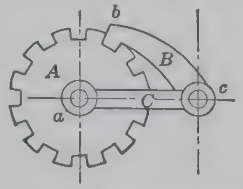

Fig. 19. Retaining pawl.

VELOCITIES IN LINKAGES may be readily determined by graphical methods. In Fig. 20 (drawn to scale) use is made of relative velocities in drawing a velocity polygon from which the linear velocities of points in the various links and the angular velocities of the links may be determined. If the angular speed *N* of the crank Q_2A is known, the linear velocity of the crankpin *A* may be calculated. *qa* represents this velocity, laid off to scale and in its correct sense. A line representing the velocity of *B* relative to *A* is drawn from *a* perpendicular to *AB*. Another line representing the velocity of *b* is drawn from *q* perpendicular to Q_4B. At the intersection of these lines locate *b*. Then *ab* represents, to the same scale as *qa* was drawn, the velocity of *B* relative to *A*, and *qb* represents the velocity of *b*. In like manner, *bc* perpendicular to *BC* is the velocity of *C* relative to *B*, and *qc* is the velocity of *C*. *cd* is perpendicular to *CD*, and *qd*, drawn parallel to the motion of *D*, is the velocity of the block *D*. The point *P* on link *AB* is located on *ab* by the proportion $ap = AP(ab/AB)$. Then the velocity of *p* is represented to scale by the line *qp*. The angular velocity of *AB* equals the linear velocity of *B* relative to *A* (*ab* to scale), divided by the length of *AB* on the machine in the same linear units as the linear units of the linear velocity of *B* relative to *A*. The angular velocity of the triangular-shaped link Q_4BC equals the linear velocity of *B* (*qb* to scale) divided by the length of Q_4B. The angular velocity of *CD* equals the linear velocity of *C* relative to *D* (*cd* to scale) divided by the length of *CD*.

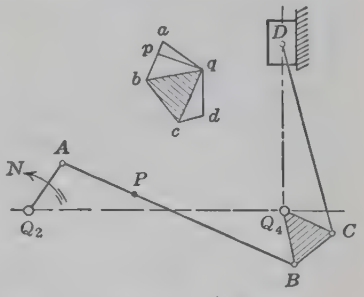

Fig. 20. Graphical determination of velocities in a linkage.

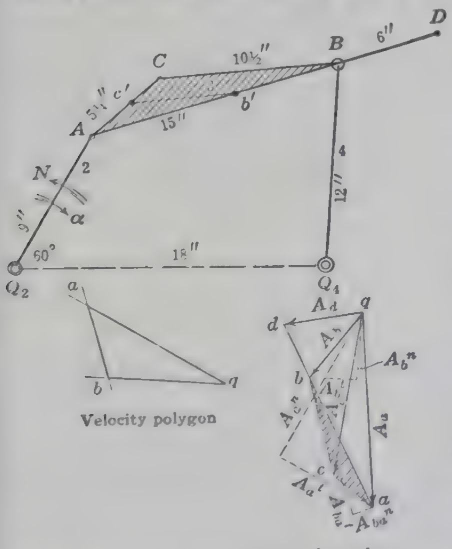

Fig. 21. Graphical method of determining accelerations in a linkage.

ACCELERATIONS IN LINKAGES may also be determined graphically. Figure 21 represents a crank and rocker mechanism drawn to scale. Choose convenient velocity and acceleration scales. Draw the velocity polygon. The acceleration polygon is drawn as follows: (1) Calculate the normal acceleration of *A*, denoted by $A_a{}^n$, from the relation $A_a{}^n = V_a{}^2/Q_2A$ and the tangential acceleration of *A*, denoted by $A_a{}^t$, from the relation $A_a{}^t = \alpha_2 \times Q_2A$. (2) Lay off $A_a{}^n$ (to scale) parallel to Q_2A and $A_a{}^t$ perpendicular to Q_2A, obtaining *qa*, the acceleration of *A*. (3) Calculate the normal acceleration of *B* relative to *A* ($A_{ba}{}^n$) from the relation $A_{ba}{}^n = V_{ba}{}^2/AB$ and the normal acceleration of *B* ($A_b{}^n$) from the relation $A_b{}^n = V_b{}^2/Q_4B$. (4) Lay off $A_{ba}{}^n$ (to scale) parallel to *BA* and draw a line perpendicular to *AB* representing the direction of the tangential acceleration of B relative to A. (5) Lay off A_b^n (to scale) parallel to Q_4B and draw a line perpendicular to Q_4B representing the direction of the tangential acceleration of B. At the intersection of these two lines representing the tangential acceleration of B relative to A and the tangential acceleration of B, locate b. Then qb represents to scale the linear acceleration of B (A_b). (6) Lay off $Ab' = ab$. Draw $b'c'$ parallel to BC. With a as a center and a radius equal to Ac', draw an arc. With b as a center and a radius equal to $b'c'$, draw an arc. At the intersection of these arcs locate c. Join a and c, and b and c. Then qc equals (to scale) the acceleration of C, A_c. (7) The point d in the acceleration polygon is located by the proportion $abd = ABD(ab/AB)$. Then qd equals (to scale) the acceleration of D, A_d. (8) The angular acceleration of link 3 is $\alpha_3 = A_{ab}^t/AB$ and the angular acceleration of link 4, $\alpha_4 = A_b^t/Q_4B$. AB and Q_4B must be the actual lengths of the links in the machine in the same linear units as the linear units in the tangential acceleration.

CORIOLIS' LAW states that when a particle is moving along a path which is also in motion the absolute linear acceleration of this particle is the vector sum of (1) the acceleration which the particle would have if the path were fixed and the particle moved only along the path, (2) the acceleration which the particle would have if the particle were fixed to the path and the path moved, and (3) a compound supplementary acceleration called Coriolis' acceleration. This compound supplementary acceleration is equal to twice the product of the velocity of the particle relative to the path and the angular velocity of the path. For a detailed discussion of this law see Ref. 1, pp. 391–395.

GRAPHICAL DETERMINATION OF VELOCITY AND ACCELERATION OF A SLIDER-CRANK MECHANISM. Figure 22 is a graphical construction, known as Klein's construction, for the determination of the velocity and the acceleration of the sliding member B. At Q erect a perpendicular to the path of travel of the slide. At the intersection of the perpendicular with the connecting rod AB (extended if necessary) locate W. With AW as a radius and A as a center, draw a circle; with a radius equal to one-half the length of the connecting rod and a center at M, the midpoint of the connecting rod, draw a circle. Join the intersections, T and J, of these two circles with the line TJ. Locate H at the intersection of TJ and a line through Q parallel to or coinciding with the path of travel of the slide. HQ is equal to the linear acceleration of the slide B to scale, and QW is equal to the linear velocity of the slide B to scale. For this construction to hold, the mechanism must be a slider-crank mechanism, with the guides stationary; the crank must rotate uniformly; the length of the crank QA on the drawing must equal to scale the linear velocity of the crankpin A; and the length of the crank QA on the drawing must equal to scale the normal acceleration of the crankpin A. The acceleration of the slide, represented by HQ, is to the same scale as the normal acceleration of A, and the velocity of the slide, represented by QW, is to the same scale as the linear velocity of the crank A. The mechanism may be drawn to any convenient scale.

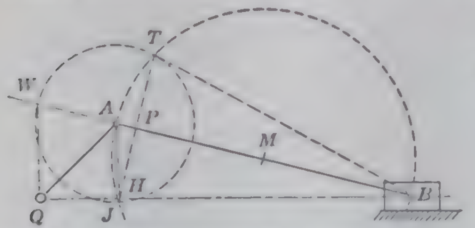

FIG. 22. Klein's construction for velocity and acceleration of slider block.

For a full discussion of linkages, see Ref. 2.

3. POWER SCREWS

THE SCREW is an inclined plane wrapped around a cylinder in such a way that the height of the plane is parallel to the axis of the cylinder. If the screw is formed on the internal surface of a hollow cylinder, it is called a nut. When force is applied to raise a weight or overcome a resistance by means of a screw and nut, either the screw or the nut may be fixed, the other being movable. The force generally is applied at the end of a wrench or lever arm, or at the circumference of a wheel. If r is the radius of the wheel or lever arm, inches, and p is the pitch of the screw, or distance between threads, that is, the height of the inclined plane for one revolution of the screw, inches, P is the applied force, pounds, and W is the resistance overcome, pounds, then, neglecting resistance due to friction,

$$2\pi r P = W p \tag{10}$$

The ratio of P to W is thus independent of the diameter of the screw. In actual screws, much of the power transmitted is lost through friction.

Efficiency of a Screw. Let α be the helix angle or angle of the thread, that is, the angle whose tangent is the pitch of the screw divided by the circumference of a circle whose diameter is the mean of the diameters at the top and bottom of the thread. Then, for a square thread,

$$\text{Efficiency} = \frac{\tan\alpha(1 - f\tan\alpha)}{\tan\alpha + f} \tag{11}$$

in which f is the coefficient of friction of the threads. The coefficient of friction is not uniform and varies with the materials used, the relative smoothness of the contact surfaces, the quality of lubrication, and the unit pressure on the threads. With rubbing velocities less than 50 fpm, unit pressures less than 14,000 psi, and average lubrication, the coefficient of friction of threads for machine oil and graphite is 0.07; for lard oil it is 0.11; and for heavy machine oil it is 0.14. Figure 23 shows the relationship between the helix angle and the efficiency of square threads. Equation 11 and Fig. 23 are for the square threads only and do not consider the friction of the collar or step by which end thrust is resisted, and which further reduces the efficiency. Considering collar friction and for square threads,

$$\text{Efficiency} = \frac{\tan\alpha(1 - f\tan\alpha)}{\tan\alpha + f + \dfrac{f_cD_c}{D_m}(1 - f\tan\alpha)} \tag{12}$$

where f_c is the coefficient of friction of the collar, D_c is the mean diameter of the thrust collar, inches, and D_m is the mean diameter at the top and bottom of the thread, inches. C. W. Ham and D. G. Ryan (Ref. 3) give the following coefficients of friction for the thrust collars on power screws:

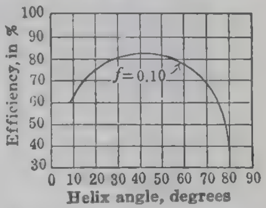

FIG. 23. Efficiency of screw threads (square) excluding collar friction.

Material	Coefficient of Running Friction	Coefficient of Starting Friction
Soft steel on cast iron	.121	.170
Hardened steel on cast iron	.092	.147
Soft steel on bronze	.084	.101
Hardened steel on bronze	.063	.081

The efficiency of a V-thread is lower than that of a square thread. Neglecting collar friction, the efficiency of a V-thread is given by the equation

$$\text{Efficiency} = \frac{\tan\alpha(\cos\theta - f\sin\alpha)}{\tan\alpha\cos\theta + f\cos\alpha} \tag{13}$$

where $\cos\theta = \dfrac{1}{\sqrt{1 + \tan^2\phi + \tan^2\alpha}}$ and ϕ = one-half the included thread angle measured on a plane through axis, degrees. If the collar friction is considered,

$$\text{Efficiency} = \frac{\tan\alpha(\cos\theta - f\sin\alpha)}{\tan\alpha\cos\theta + f\cos\alpha + \dfrac{f_cD_c}{D_m}(\cos\theta - f\sin\alpha)} \tag{14}$$

THE WORM GEAR (Fig. 24), essentially an endless screw, is used to convert motion at high speed into motion at slow speed. When the handle P describes a complete circumference, the pitch line of the worm wheel moves through a distance equal to the pitch of the screw, and the weight W is lifted a distance equal to the pitch of the screw multiplied by the ratio of the diameter of the axle to the diameter of the pitch circle of the wheel. The ratio of the applied force to the weight lifted, or resistance, is inversely as the velocities, friction not being considered; but the friction in the worm gear is usually very great, amounting sometimes to three or four times the useful work done.

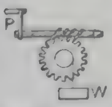

FIG. 24. Worm gear.

If v = the distance through which the force P acts in a given time, say one second, and V = distance the weight W is lifted in the same time, r = radius of the crank or wheel through which P acts, t = pitch of the screw, and also pitch of the teeth of the worm wheel, d = diameter of the axle, and D = diameter of the pitch line of the wheel,

$$v = \frac{6.283r}{t}\frac{D}{d}V \tag{15}$$

$$V = \frac{vtd}{6.283rD} \tag{16}$$

$$Pv = WV + \text{Friction} \tag{17}$$

COMPOUND AND DIFFERENTIAL SCREWS. A compound screw consists of a right-hand and a left-hand thread wound on the same or on different cylinders. When wound on the same cylinder (Fig. 25a) two nuts are employed. When wound on different cylinders (Fig. 25b) one nut is employed. Usually both threads have the same pitch. Each revolution of the screw causes the two nuts to move toward one another a distance equal to the sum of the pitches. Thus two fine threads will give the same relative advance as one coarse thread of double the pitch.

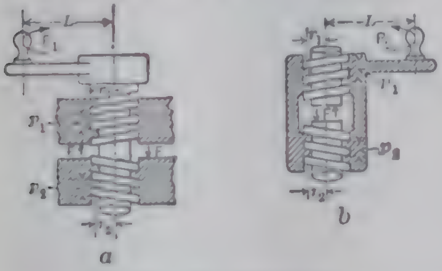

Fig. 25. Compound screw.

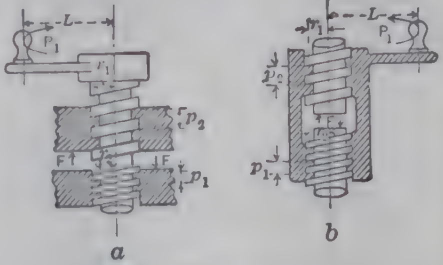

Fig. 26. Differential screw.

A differential screw comprises two threads of the same hand, but of different pitches, wound on the same or different cylinders. See Figs. 26a and 26b. One revolution of the screw causes the nuts (Fig. 26a) to move toward each other a distance equal to the difference of the pitches. One revolution of the nut (Fig. 26b) causes the screws to approach by the same distance. Thus the use of two coarse threads gives the same relative advance as one fine thread.

Efficiency. The following formulas give the efficiency of screws with square threads. In these formulas, r_1, r_2 = mean radius (to half depth of thread), inches; c_1, c_2 = mean circumference of screw, inches; p_1, p_2 = pitch of thread, inches; p = equivalent pitch, inches; f = coefficient of friction of threads; f' = coefficient of friction of collar; L = length of wrench, inches; P_1 = pull on wrench, pounds; F = force transmitted by screw, pounds; E = efficiency. Then

For simple screws:

To raise load (Fig. 27a),

$$P_1 = \frac{F}{L}\left(f'x + \frac{p_1 + fc_1}{c_1 - fp_1} r_1\right) \tag{18}$$

To lower load (Fig. 27b),

$$P_2 = \frac{F}{L}\left(f'x + \frac{fc_1 - p_1}{c_1 + fp_1} r_1\right) \tag{19}$$

in which x = mean radius of collar = $(k_2 + k_1)/2$. If $f = 0$,

$$P = \frac{F}{L}\frac{p_1}{6.2832} \quad \text{and} \quad E = \frac{P}{P_1} \tag{20}$$

For compound screws (see Fig. 25):

$$P_1 = \frac{F}{L}\left(\frac{p_1 + fc_1}{c_1 - fp_1} r_1 + \frac{p_2 + fc_2}{c_2 + fp_2} r_2\right) \tag{21}$$

If $f = 0$,

$$P = \frac{F}{L}\frac{p_1 + p_2}{6.2832} \quad \text{and} \quad E = \frac{P}{P_1} \tag{22}$$

For differential screws (see Fig. 26):

$$P_1 = \frac{F}{L}\left(\frac{p_1 + fc_1}{c_1 - fp_1} r_1 + \frac{fc_2 - p_2}{c_2 + fp_2} r_2\right) \tag{23}$$

If $f = 0$,

$$P = \frac{F}{L}\frac{p_2 - p_1}{6.2832} \quad \text{and} \quad E = \frac{P}{P_1} \tag{24}$$

For V-threads use $1.15f$ instead of f.

The load that may be lifted or the force that may be exerted by any of these screws is so much affected by friction that efficiency rarely is as high as 70%. It often is less than 30% for simple screws, and may be less than 5% for differential screws.

The chief use of the differential screw is to obtain very small movements in precision equipment. Its inefficiency as a means of transmitting power is illustrated by the differential screw punch of Fig. 28.

Differential Screw Punch. Figure 28 is a diagram of a differential screw punch in which the pitch of the outer thread is 1/3 in. and that of the inner thread 2/7 in., giving an equivalent pitch of 1/21 in. By jamming the bottom of the outer screw against the top of the inner screw, the device operates as a simple screw punch, with an advance of 1/3 in. per revolution. The punch was used both as a differential screw punch and a simple screw punch to punch 11/16-in. holes in 1/4-in. plate, requiring a force of 27,000 lb. The results with the device used as a differential screw punch were disappointing. The efficiency as computed by eqs. 23 and 24 and as actually measured were

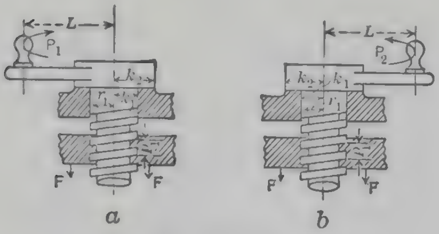

FIG. 27. Simple screw.

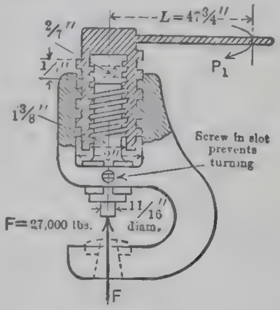

FIG. 28. Differential screw punch.

	Computed		Actual	
	Pull on Lever	Efficiency	Pull on Lever	Efficiency
As a differential punch	92 lb	4.6%	95 lb	4.5%
As a simple punch	83 lb	36.1%	82 lb	36.7%

4. CAMS

THE CAM is a revolving inclined plane. It may be either an inclined plane wrapped around a cylinder in such a manner that the height of the plane is radial to the cylinder, such as the ordinary lifting cam used in stamp mills (Fig. 29) or it may be an inclined plane curved edgewise and rotating in a plane parallel to its base (Fig. 30). The relation of the weight lifted to the applied force is calculated in the same manner as for the screw. (See p. 7-08.)

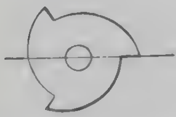

FIG. 29. Lifting cam.

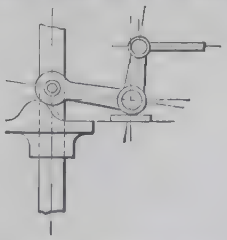

FIG. 30. Edgewise cam.

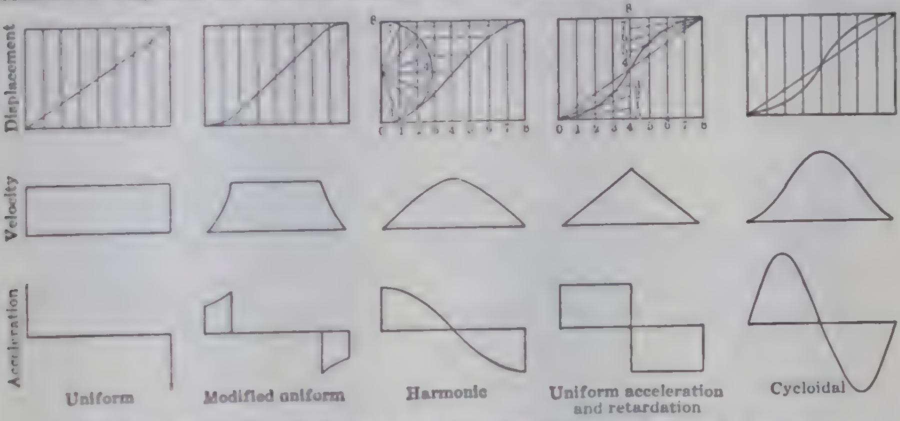
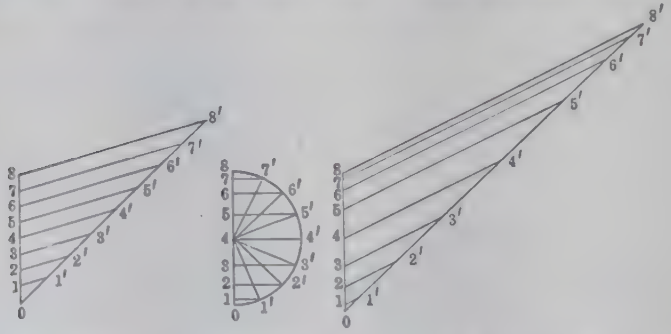
Cam Motions. The motion imparted by a cam to its follower may follow some law of motion or be such as to cause the follower to be at predetermined positions without regard to fulfilling some definite law of motion. A *displacement diagram*, with time or cam positions as abscissas and follower displacements as ordinates, is useful in studying the motions and in laying out the cam contour. If the motion of the follower does not follow a definite law of motion a displacement diagram is essential to obtain a curve of the motion between the points which represent the predetermined positions of the cam. When the motion imparted to a follower fulfills some law of motion no displacement curve is necessary for the laying out of the cam contour. Velocity and acceleration diagrams for the follower are useful in analyzing the motion and forces in the cam mechanism. With high speeds and accelerations, high forces will result, causing deflections in the linkage and poor operation of the parts controlled by cams. Cam motions are often modified so as to reduce the accelerations and the resulting shocks. Figure 31 shows the displacement, velocity, and acceleration diagrams for uniform motion, modified uniform motion, harmonic motion, uniformly accelerated and retarded motion (often called gravitational motion or parabolic motion), and cycloidal motion.



Uniform **Modified uniform** **Harmonic** **Uniform acceleration and retardation** **Cycloidal**

FIG. 31. Displacement, velocity, and acceleration diagrams for cam followers.

Motion Layout. A cam in its 360-degree rotation may raise and/or lower its follower by imparting one or several types of motion during various increments of the 360-degree rotation of the cam. For example, the follower may be raised a distance by uniform motion for one-fourth turn of cam, then raised another distance one-fourth turn by harmonic motion, and then lowered to its original position during the last half turn of the cam by parabolic motion. In laying out the motions of the follower, a displacement diagram may be used or the motion may be laid off directly on the path of the follower by choosing the same number of increments of the motion of follower and angular increments of the cam during which the desired motion is imparted. Figure 32 shows the most common types of motions for followers. In each case 0–8 is the distance the follower is raised or lowered, the numerals 1, 2, 3, etc., are the positions of the follower at the corresponding angular position of the cam, and 1′, 2′, 3′, etc., are the divisions of motion laid off on the construction lines. Figure 32*a* shows the method of laying out uniform motion where equal distances are traveled in equal units of time. Figure 32*b* shows the method of laying out simple harmonic motion; the follower is raised from 0 to 1 in one unit of time, from 1 to 2 in the second unit of time, etc., and the distance 0–8 is traversed with simple harmonic motion. Figure 32*c* shows the method of laying out uniformly accelerated and retarded motion where the follower is raised from its starting point as the square of the time ($s = at^2/2$, where s = displacement, a = constant acceleration, and t = time). The total spaces traveled will be proportional to 1, 4, 9, 16, etc., and successive spaces traveled in equal time units will be in the proportion 1, 3, 5, 7, etc. For retardation, the increments will be 7, 5, 3, 1.



(*a*) **Uniform** (*b*) **Harmonic** (*c*) **Uniform acceleration and retardation**

FIG. 32. Layout of uniform, harmonic, and uniform acceleration and retardation motions.

Laying Out a Uniform-motion Cam. In Fig. 33 a circle of radius OC, equal to the smallest radius of the cam, is drawn. The vertical radius is prolonged beyond the circle to B. The distance 0–6, equal to the maximum movement of the follower, is laid off on OB from its intersection with the circle, and divided into any convenient number of equal parts. The semicircle to the right of OB is divided into the same number of equal arcs, and radii are drawn through the points of division. Then with O as a center, and with radii equal to O–1, O–2, O–3, etc., arcs are drawn intersecting the corresponding radii at a, b, c, etc. The smooth curve drawn through these points is the profile of the cam. The profile of the cam to the left of OC is identical, and is drawn in the same manner.

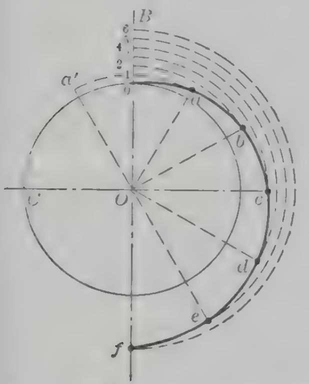


FIG. 33. Uniform-motion cam with point follower.

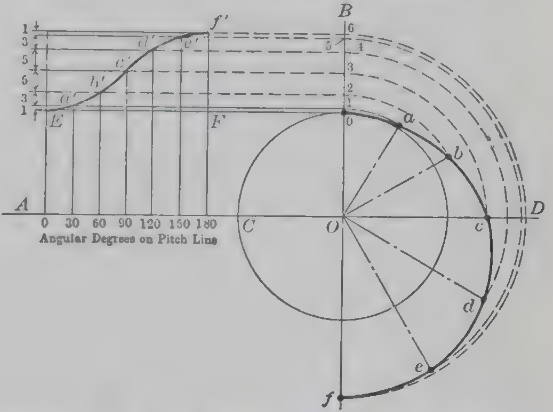

FIG. 34. Cam with uniform acceleration and retardation, employing point follower.

Laying Out a Cam with Uniform Acceleration and Retardation. (See Fig. 34.) Draw AD, and from O as a center, with radius OC equal to the smallest radius of the cam, draw a circle. Draw fOB perpendicular to AD. Draw the tangent $0FE$ parallel to AD. Divide the semicircle to the right of fOB into any convenient number of equal arcs, and draw radii through the points of division. Lay off on AC equal spaces corresponding to the arcs, and erect ordinates at the points of division. Assume a value for the increment or decrement of motion. In the present case it is 2. Hence, with the semicircle divided into 30-degree arcs, the relative motion of the follower over the successive arcs will be 1, 3, 5, 5, 3, 1. Note that the motion over the first and last arcs is one-half the value of the assumed increment. Make $f'F$ equal to the total movement of the follower. It also is equal to the sum of the increments and decrements of motion, viz., $1 + 3 + 5 + 5 + 3 + 1 = 18$. The length above EF of the several ordinates will be

Angular degrees	0	30	60	90	120	150	180
Length, fraction of fF	0	$^1/_{18}$	$^4/_{18}$	$^9/_{18}$	$^{14}/_{18}$	$^{17}/_{18}$	$^{18}/_{18}$

Denote these lengths by points a', b', c', etc., and draw $a'1$, $b'2$, etc., parallel to EF, intersecting OB at 1, 2, 3, etc. The procedure from this point is the same as for the uniform-motion cam.

Laying Out Cycloidal-motion Cam. Figure 35 shows the method of laying out a cam with cycloidal motion

$$s = \frac{L}{\pi}\left(\frac{\pi\theta}{\beta} - \frac{1}{2}\sin\frac{2\pi\theta}{\beta}\right)$$

where s = displacement of follower per interval of time, L = total displacement of follower, θ = angular displacement of cam from starting point, and β = total angle through which cam turns to cause the follower to move L distance.

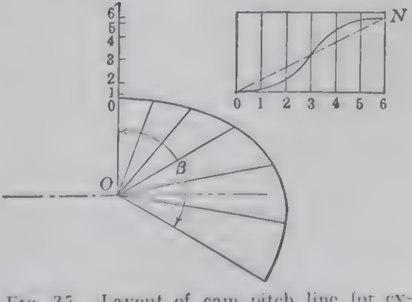

FIG. 35. Layout of cam pitch line for cycloidal motion.

A plate cam on a shaft whose axis is at O is to turn counterclockwise and cause motion to a follower. The follower is to move along the straight line from 0 to 6 while the cam turns 120 degrees. Let O–0 = 2 in. and 0–6 = L = 1 $^1/_2$ in. Since the motion of the follower takes place while the cam turns 120 degrees, $\beta = 2\pi/3$. When these values are substituted the equation becomes

$$s = \frac{1.5}{\pi}\left(\frac{\pi\theta}{2\pi/3} - \frac{1}{2}\sin\frac{2\pi\theta}{2\pi/3}\right) \tag{25}$$

$$= 0.478\left(\frac{3\theta}{2} - \frac{1}{2}\sin 3\theta\right)$$

Points on the cam pitch line will be found for each of six equal subdivisions of β, hence θ will have successive values of $(2\pi/3) \div 6$, $(4\pi/3) \div 6$, $(6\pi/3) \div 6$, ... The points O, 0, and 6 having been located on the drawing, the next step is to construct the displacement diagram with its x-axis perpendicular to 0–6 and passing through 0 in order that the ordinates may be projected directly on to the line 0–6.

To construct the displacement diagram it will be easier to use the two terms of eq. 25 separately. The first term, $0.478(3\theta/2)$, will give a straight line. Choose some distance 0–1 to represent the equal subdivisions of β and lay it off six times along the x-axis since six divisions of β are used. θ will have values of $\beta/6$, $2\beta/6$, $3\beta/6$, . . . , and since $\beta = 2\pi/3$ the values of θ will be $\pi/9$, $2\pi/9$, $\pi/3$, $4\pi/9$, $5\pi/9$, $2\pi/3$.

Erect ordinates at the points 1, 2, . . . and on the last ordinate, 6, measure up the distance $6\text{–}N = 0\text{–}6 = L$. Draw the straight line 0–N. This is the curve for the term $0.478(3\theta/2)$. For division 1 the second term $0.478(-\frac{1}{2}\sin 3\theta)$ becomes $0.478(-\frac{1}{2}\sin\pi/3) = -0.21$. That is, the actual curve cuts the ordinate at point 1 at a distance 0.21 in. below the line 0–N. The other points on the curve are determined in like manner. The ordinates are now transferred to the line 0–6, and the pitch line of the cam is constructed as in previous examples.

Cam with Offset Follower (Fig. 36). Draw the path of the follower AF in its position relative to the center O of the cam, and divide it according to the character of motion desired. (See Figs. 31 and 32.) With O as a center and AO as a radius describe a circle. Starting at A, divide it at a', b', c', etc., to correspond to the positions 1, 2, 3, etc., of the follower. With radius OC equal to the offset (perpendicular distance from OB to AF), draw the circle ECG. With O as a center, with radius equal to $O1$, draw from point 1 on the follower path the arc $1a$. From point a' draw a tangent $a'a''$ to circle ECG, intersecting the arc $1a$ at a. Similarly draw arcs $2b$, $3c$, etc., and tangents $b'b''$, $c'c''$, etc. The intersection of the arcs and tangents at a, b, c, etc., are points on the pitch line of the cam.

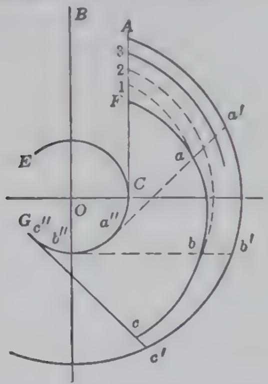

FIG. 36. Cam with offset follower.

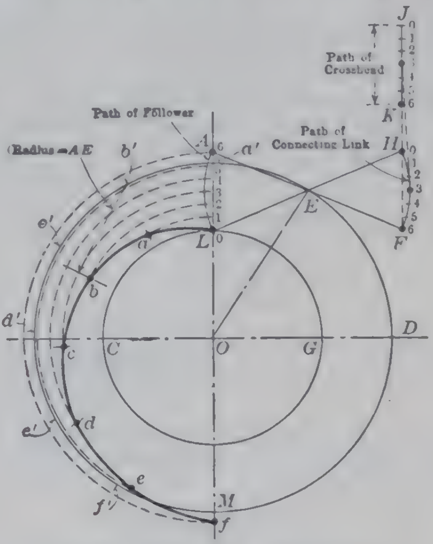

FIG. 37. Cam with rocker follower.

Cam with Follower on Rocker Arm (Fig. 37). From center O, with radius OC equal to smallest radius of cam, draw the circle CG. Draw the path of the cross head JK in its proper relative position to cam center O, and subdivide it according to the type of motion desired. (See Figs. 31 and 32.) Locate the center E of the rocker arm in its position relative to cam center O. Join the point L, on the line AO, with E and prolong LE to the opposite end H of the rocker arm. With E as a center, describe the arcs HF and AL. Divide arc HF to correspond to divisions on the path of the cross head, by striking arcs from points 0, 1, 2, etc., on JK with a radius JH. Transfer these points to arc AL. With

O as a center, and *OE* as a radius, draw circle *DEM*, and divide each semicircle at *a′*, *b′*, *c′*, etc., to correspond with the divisions on *JK*, starting the divisions at *E*, which corresponds to point 0 on *AL*. From *O* as a center, with radii of *O*1, *O*2, *O*3, etc., draw arcs 1*a*, 2*b*, 3*c*, etc. From points *a′*, *b′*, *c′*, etc., with radius equal to *LE*, strike arcs intersecting arcs 1*a*, 2*b*, 3*c*, etc., at *a*, *b*, *c*, etc. The intersections *a*, *b*, *c*, etc., are points on the pitch line of the cam.

Note. In the examples of cam layout, Figs. 36 and 37 a uniform-motion cam has been considered. The procedure for any other motion would be identical, except that the points of division of the path of the follower would be determined as illustrated in Figs. 31 and 32.

Correction for Roller Follower. A roller follower must be used with cams, unless the force to be transmitted is small. The pitch line of the cam as determined by the above methods then must be corrected. Figure 38 shows the method of making such corrections. The pitch line as determined above is *ab*. From the center *O* draw radii *Oc*, *Od*, etc. With the points of intersection of the radii with *ab* as centers, draw arcs of radius equal to the radius of the roller follower. The cam profile is a smooth curve drawn tangent to these arcs. In Fig. 38 the line *HG* is the profile of a plain cam, and the lines *HG* and *JK* are the boundaries of the slot of a slotted cam.

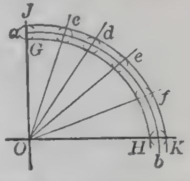

Fig. 38. Profile for roller follower.

Correction for Flat-faced Follower. Flat-faced followers are widely used. The pitch line of the cam as determined by the previous methods must be corrected. Figure 39 shows the method of making such corrections. Assume the pitch line *ab* to be determined as previously discussed. From the center *O* draw radii *Oc*, *Od*, etc. At the points of intersection of the radii with *ab*, draw the straight lines 1–2, 3–4, etc., making the same angles with the radii as the follower face *mn* makes with *Oa* (in this case 90 degrees). The surface of the cam will be the curve *ap* drawn tangent to the lines 1–2, 3–4, etc. If the flat face of the follower makes some other angle with the reference line *Oa*, the lines 1–2, 3–4, etc., should be drawn through the intersection of the radii *Oc*, *Od*, etc., and the pitch line at this same angle with *Oc*, *Od*, etc.

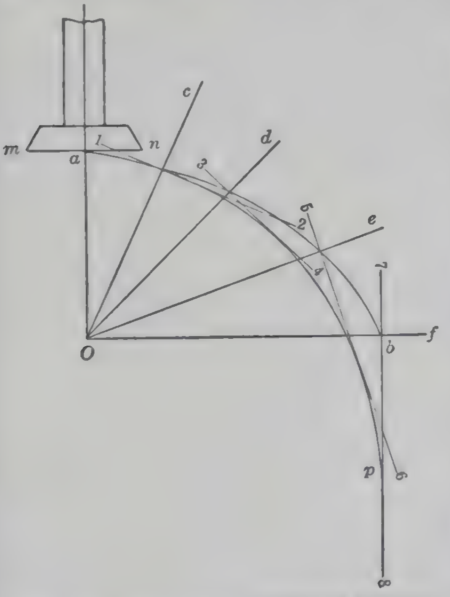

Fig. 39. Cam profile for flat-faced follower.

Cylindrical cams comprise a cylinder with a slot cut in the cylindrical surface. The variation in the slope of the slot causes a roller projecting into it to be moved as the cylinder rotates about its axis. Any desired variation in motion can be obtained by appropriate variation of the slot. Figure 40 shows the method of laying out a cam to give a uniformly accelerated and retarded forward motion and a uniform return motion in two revolutions of the cam. The line *AB* represents to scale the total movement in one direction of the follower. The line *AA′*, to the same scale, represents the circumference of the cam. The rectangle *AA′B′B* therefore represents the developed surface of the cam. Divide *AB* into the number of equal spaces necessary to represent the desired sequence of acceleration and deceleration increments. Erect ordinates at the division points and locate on them the points of the pitch line. (See Cams with Uniform Acceleration and Retardation, p. 7-13.) Draw the pitch line *AB′* for the forward motion of the follower. The pitch line of the return path is a straight line from *B* to *A′*. Inasmuch as strictly uniform motion would cause shock, the return pitch line is drawn between points slightly short of *B* and *A′*, and joined to *B* and *A′* by arcs. Figure 41 shows the layout of a cam that gives a harmonic forward motion and a uniform return motion to the follower in a single revolution.

Cylinder cams also can be designed to give a variety of motions in sequence, during several revolutions. The rectangle representing the developed surface of the cam is divided into half as many parts as the number of revolutions per cycle. The pitch line for that portion of the forward motion of the follower that is to take place during each revolution then is laid out, by the methods described above, in the portion of the rectangle corresponding to the revolution under consideration. Figure 42 shows the layout of a cam to give the following cycle of motions in four revolutions: (1) $^3/_4$ revolution, uniform acceleration and deceleration; (2) $^1/_4$ revolution, dwell; (3) $^3/_4$ revolution, uniform acceleration and deceleration; (4) $^1/_4$ revolution, dwell; (5) 2 revolutions, return.

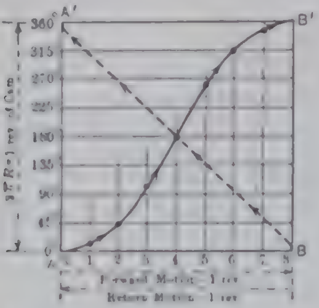

FIG. 40. Cylindrical cam layout, for two revolutions per cycle.

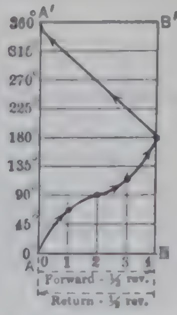

FIG. 41. Cylindrical cam layout, for one revolution per cycle.

Minimum radius of curvature of the pitch line at any point should not be less than $d + 1/8$ in., where d = diameter of cam roller in inches. Otherwise there will be a loss of rise of the follower which will vary in accordance with the sharpness of the angle of intersection of two adjoining curves on the cam.

Rollers for Cylinder Cams. The preferred form of rollers that work in the slot of a cylinder cam is the frustum of a cone, with a corresponding taper of the cross section of the slot. Straight rollers do not have a true rolling action because of the difference in linear velocity of the top and the bottom of the slot. This sliding of a portion of the roller tends to wear both roller and slot, resulting in eventual backlash and faulty action.

The method of determining the taper of roller and slot is shown in Fig. 43. Draw AB equal to the total throw of the cam. Draw AC perpendicular to AB and of a length equal to the length of pitch line on the surface of the cam through which correct cam action is necessary; for example, lengths AD or BE in Fig. 42. Lay out CD equal to the length of the pitch line at the bottom of the slot. This may be determined by redrawing, for example, Fig. 42, making $AA' = 2\pi r$, where r = diameter of cam cylinder at bottom of slot. At D, draw DE parallel to AB and equal in length to AB. Then CB equals the developed length of the helix traversed by the top of the roller and CE equals the developed length of the helix traversed by the bottom of the roller. If $CB = a$, $CE = b$, D = diameter of roller at top, and d = diameter of roller at bottom, $d = bD/a$.

FIG. 42. Cylindrical cam layout, for four revolutions per cycle.

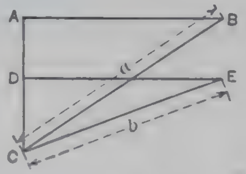

FIG. 43. Construction for determining cylindrical cam slot and roller dimensions.

The head of the pin on which the roller is mounted should be recessed into the roller at least $^1/_{64}$ in. to avoid sliding contact with the bottom of the slot.

5. HOISTING TACKLE

Pulley Blocks. Let P = force applied, or pull; W = load lifted, or resistance. In the simple pulley A (Fig. 44A), the point P on the pulling rope descends the same amount that the load is lifted, therefore $P = W$. In Figs. 44B and 44C the point P moves twice as far as the load is lifted, therefore $W = 2P$. In Figs. 44B and 44C there is one movable block, and two plies of the rope engage with it. In Fig. 44D there are three sheaves in the movable block, each with two plies engaged, or six in all. Six plies of the rope, therefore, are shortened by the same amount that the load is lifted and the point P moves six times as far as the load; consequently $W = 6P$. In general, the ratio of W to P is equal to the number of plies of the rope that are shortened, and also is equal to the number of plies that engage the lower block. If the lower block has two sheaves and the upper three, the end of the rope is fastened to a hook in the top of the lower block; then there are five plies shortened instead of six, and $W = 5P$. If V = velocity of W and v = velocity of P, then in all cases $VW = vP$, whatever the number of sheaves or their arrangement. If the hauling rope, at the pulling end, passes first around a sheave in the upper or stationary block, the direction in which the rope is led from this block to the point at which the pull on the rope is applied is immaterial. If, however, it first passes around the movable block, it is necessary that the pull be exerted in a direction parallel to the line of action of the resistance, or a line joining the centers of the two blocks, in order to obtain the maximum effect. If the rope pulls on the lower block at an angle, the block will be pulled out of the line drawn between the load and the upper block, and the effective pull will be less than the actual pull on the rope in the ratio of the cosine of the angle the pulling rope makes with the vertical, or line of action of the resistance, to unity.

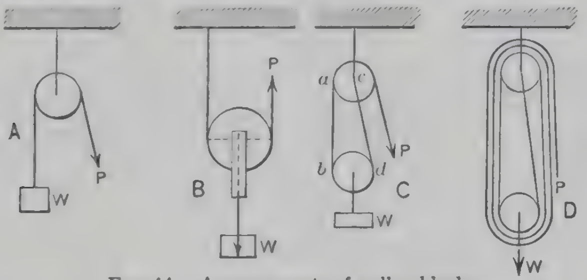

Fig. 44. Arrangements of pulley blocks.

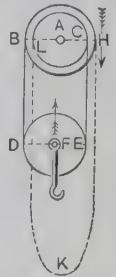

Fig. 45. Differential pulley.

Differential Pulley (Fig. 45). Two pulleys, B and C, of different radii, rotate as one piece about a fixed axis, A. An endless chain, $BDECLKH$, passes over both pulleys. The rims of the pulleys are shaped so as to hold the chain and prevent it from slipping. One of the bights or loops DE, in which the chain hangs, passes under and supports the running block F. The other loop or bight, HKL, hangs freely, and is called the hauling part. It is evident that the velocity of the hauling part is equal to that of the pitch circle of the pulley B.

In order that the velocity ratio may be exactly uniform, the radius of the sheave F should be an exact mean between the radii of B and C.

Consider that the point B of the cord BD moves through an arc whose length is AB; during the same time the point C of the cord CE will move downward a distance AC. The length of the bight or loop $BDEC$ will be shortened by $AB - AC$, which will cause the pulley F to be raised half this amount. If P is the pulling force on the cord HK, and W the weight lifted at F, then

$$P \times AB = W \times 1/2\,(AB - AC) \tag{26}$$

The length of chain required for a differential pulley is half the circumference of A + half the circumference of B + half the circumference of F + twice the greatest distance of F from A + the least length of loop HKL. The last quantity is fixed according to convenience.

A wheel and axle, or windlass, resembles two pulleys on one axis having different diameters. If a weight is lifted by means of a rope wound over the axle, the force being applied at the rim of the wheel, the action is like that of a lever of which the shorter arm is equal to the radius of the axle plus half the thickness of the rope, and the longer arm is equal to the radius of the wheel. A wheel and axle is, therefore, sometimes classed as a perpetual lever. If P = the applied force, D = diameter of the wheel, W = the weight lifted, and d = diameter of the axle + the diameter of the rope, $PD = Wd$.

6. THE GYROSCOPE

The gyroscope is in effect a heavy disk spinning rapidly on its axis, and so mounted that its center is stationary while the axis may take any position whatever. See Fig. 46. A characteristic of the gyroscope, which is utilized in stabilizers to prevent the rolling of ships, in the gyro-compass, in monorail cars, etc., is that when the disk is spinning in a given plane, it resists any attempt to cause it to spin in a different plane. In Fig. 47, the disk of radius r spins about the axis ZZ. The disk lies in the plane $QRST$, and the axis ZZ in plane $ABCD$, perpendicular to $QRST$. Now let a force F be applied at one end of the axis ZZ, tending to move the disk about its stationary center O into a plane at an angle to $QRST$. The movement of the axis in the direction of F will set up a force G, perpendicular to plane $ABCD$ and parallel to plane $QRST$. If this *gyroscopic reaction* G is resisted by some means, as, for instance, having the ends of the axis bear against a guide parallel to $ABCD$, the resistance G', equal and opposite to G, will tend to impede movement in the direction of F. The direction of G is determined by considering F as a pull applied to the end of the axis. Then G will act in the same direction as a point on the disk, in the plane of F and on the same side of the axis, is moving.

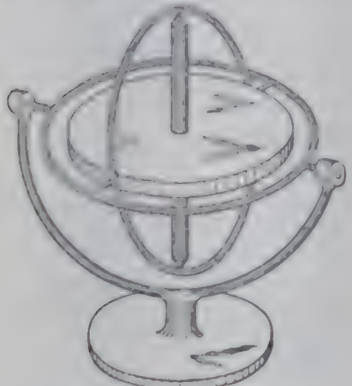

Fig. 46. Gyroscope.

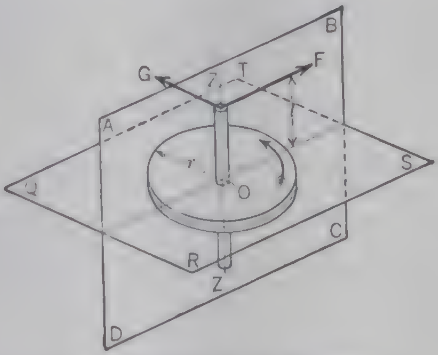

Fig. 47. Forces in the gyroscope.

The magnitude of the forces is as follows. Let F = force applied to move the axis, m = mass of the disk = w/g, R = its radius of gyration, a = acceleration at any instant due to application of force F, l = length of lever arm = OZ, N = rpm of disk, v = velocity corresponding to acceleration a. Then $F = 1/2\, mR^2a$ and

$$Gl = mR^2 \left(\frac{\pi N}{30}\right) vl$$

For a mathematical analysis of the forces in the gyroscope and a discussion of its applications, see Ref. 1, p. 378, and Ref. 4.

MECHANICS

In the design of structures and machines, certain equations and relations developed by the science of mechanics frequently must be used. The more commonly used formulas are given below. For a mathematical discussion of these relations, see Eshbach, *Handbook of Engineering Fundamentals*, Section 4.

7. CENTER OF GRAVITY

The center of gravity of a body or system of bodies rigidly connected is the point about which, if suspended, all parts will be in equilibrium, i.e., without tendency to rotate. In bodies of uniform density, the center of gravity is the center of magnitude.

The center of gravity of *two bodies* is at a point between them, whose distance from their respective centers of gravity is inversely proportional to their weights. The center of gravity of *more than two bodies* is located by determining the center of gravity of two of them; then considering these two as a single body whose weight is concentrated at their common center of gravity, the center of gravity with reference to the third body is located. The process is repeated until all the bodies in the system have been considered.

The center of gravity of regular figures, whether plane or solid, is the same as their geometrical center. The center of gravity of symmetrical figures lies on the axis of symmetry. The center of gravity may be determined by suspending a body or figure from two different points and dropping a plumb line from the point of suspension. The intersection of the plumb lines will be the center of gravity.

The location of the center of gravity of the more common lines, areas, and solids is:

LINES. Straight Line. At middle point of the line.

Semicircumference. On middle radius R, at distance $0.6366R$ above diameter.

Quadrant. On middle radius R, at distance $0.90028R$ from center.

Circular arc of subtended angle α, on middle radius R, at distance from center of $(R \sin {}^1/_2\alpha)/({}^1/_2\alpha)$, where α is in radians.

Cycloid, generated by circle of diameter D, on perpendicular to middle of base, and ${}^2/_3\,D$ above base.

PLANE FIGURES. Triangle. At the intersection of two medians L_1 and L_2, or at a distance of ${}^1/_3\,L$ above the base.

Parallelogram. At intersection of diagonals.

Trapezium or Trapezoid. At the intersection of the two lines joining the centers of gravity of the two triangles formed by drawing first one diagonal and then the other.

Sector of circle of radius R, chord C, arc L; on radius bisecting arc, at $(2CR/3L)$ from center.

Semicircle. On middle radius, $0.4244R$ from center.

Quadrant. On middle radius, $0.600R$ from center.

Segment of circle of chord C and area A, $C^3/12A$ from center.

Parabolic Surface. In the axis, three-fifths of its length from vertex.

Semiparabola (surface). Three-fifths of axis from vertex, and three-eighths of semibase from axis.

Quadrant of ellipse of semi-axes a and b. At intersection of parallels to the axes a and b, and distant from them, respectively, $[b - {}^4/_3\,(b/\pi)]$ and $[a - {}^4/_3\,(a/\pi)]$.

SOLID BODIES. Prism or Cylinder (parallel bases). At middle point of line joining centers of gravity of the bases.

Oblique frustum of right circular cylinder of radius R mean height H. In the plane of symmetry at $[{}^1/_2\,H + (R^2 \tan \alpha/8H)]$ above base, where α is angle of oblique section to the base, and at $({}^1/_4\,R^2 \tan \alpha/H)$ from the axis.

Cone or Pyramid. In the axis, one-fourth of its length above the base.

Paraboloid. In the axis, two-thirds of its length from the vertex.

Frustum of Cone or Pyramid. In axis, at distance above base of

$$\frac{a}{4} - \frac{3a'^3}{4(a^2 + aa' + a'^2)}$$

where a = length of line from vertex of complete cone to center of gravity of base and a' = that portion of it between vertex and top of frustum.

Hemisphere. On radius R, perpendicular to base, at ${}^3/_8\,R$ above base.

Hollow Hemisphere. Radii R and r. On radius perpendicular to base at

$$\frac{{}^3/_8\,(R^4 - r^4)}{R^3 - r^3} \text{ above base}$$

Segment of Sphere. Radius R; height of segment, H. On radius perpendicular to base, at $[{}^3/_4\,(2R - H)^2/(3R - H)]$.

Sector of Sphere. Radius R; height of segment subtended by sector, H. On the middle radius, at ${}^3/_8\,(2R - H)$ from center.

Ellipsoid of semi-axes, A, B, and C. If an ellipsoid is divided into eight parts by planes passing through each axis, the center of gravity of each part will lie in the point of intersection of three planes parallel to A, B, and C, and at a distance from them respectively, of ${}^3/_8\,B$, ${}^3/_8\,C$, and ${}^3/_8\,A$. See Fig. 1.

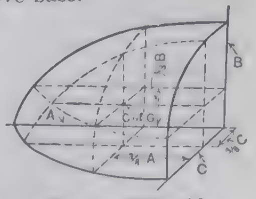

FIG. 1. Ellipsoid.

8. MOMENT OF INERTIA

THE MOMENT OF INERTIA OF A BODY with respect to an axis is the algebraic sum of the products of the weight of each elementary particle multiplied by the square of its distance from the axis. If $w_1, w_2 \cdots w_n$ represent the weights of the several particles, and $r_1, r_2 \cdots r_n$, their respective distances from axis XX, then the moment of inertia with respect to the axis XX is $I = w_1r_1^2 + w_2r_2^2 + \cdots w_nr_n^2$. The unit of the mass moment of inertia is pound-feet^2 if mass is expressed in pounds and dimensions of body in feet. I is least when the axis passes through the center of gravity of the body.

Moment of inertia as applied to areas, as the cross section of structural beams, equals ar^2 where a is any elementary area. The unit of the area moment of inertia is inches^4 or feet^4 if the dimensions of the body are expressed in inches or feet, respectively. Moments of inertia of the more commonly used bodies, about different axes, are given in Table 1.

Table 1. Moment of Inertia of Commonly Used Bodies

W = weight of body; w = weight of elementary unit of body; d = distance of center of gravity of body from axis.

	Solid rod, axis perpendicular to axis of rod, $I = W[(l^2/12) + d^2]$		Solid cylinder, axis coincident with axis of cylinder, $I = WD^2/8$
	Hollow cylinder about its axis, $I = 1/8\, W(D_1^2 + D_2^2)$ Thin hollow cylinder, $I = 1/4\, WD_1^2$		Solid cylinder, axis perpendicular to axis of cylinder, $I = W\left(\frac{D^2}{16} + \frac{l^2}{12} + d\right)$
	Thin circular plate, axis in its own plane, $I = W[(r^2/4) + d^2]$		Thin circular plate, axis perpendicular to plate, $I = W[(r^2/2) + d^2]$
	Circular ring, axis perpendicular to plane, $I = W[1/2(R^2 + r^2) + d^2]$		Circular ring about axis XX, $I = w\pi^2Rm^2(R^2 + 5/4m^2)$ About axis YY, $I = 1/2\, w\pi^2Rm^2(4R^2 + 3m^2)$
	Solid sphere about diameter, $I = 2/5\, Wr^2$		Hollow sphere about diameter, $I = 8/15[w\pi(R^5 - r^5)]$ Thin sphere, $I = 2/3\, WR2$
	Rectangular prism, axis through c. of g. perpendicular to face mn, $I = 1/12\, W(m^2 + n^2)$		Right circular cone, axis XX, $I = 3/5\, W(1/4\, r^2 + h^2)$ About its axis of revolution, $I = 3/10\, Wr^2$

Moment of Inertia about Parallel Axes. If the moment of inertia I of an area or solid, about an axis through the center of gravity, is known, its moment of inertia I' about any parallel axis may be found by the formula $I' = I + (d^2 \times A)$, where d = distance between the two axes and A = the area or weight. Moments of inertia of sections are given on pp. 8-09 and 8-10.

Polar Moment of Inertia. If the moments of inertia of an area with respect to two rectangular axes in the same plane are known, its moment of inertia about an axis perpendicular to this plane, and passing through the intersection of the axes, is equal to the sum of the moments of inertia about the two rectangular axes. This latter, known as the polar moment of inertia, is designated by J. If I and I' are the moments of inertia about the rectangular axes XX and YY, $J = I + I'$.

Moment of Inertia about Any Axis. If b = breadth and h = depth of a rectangular section, its moment of inertia about its central axis (parallel to the breadth) is $^1/_{12}bh^3$; and about one side is $^1/_3bh^3$. If a parallel axis exterior to the section is taken, and d = distance of this axis from the farthest side and d_1 = its distance from the nearest side, $(d - d_1) = h$, the moment of inertia about this axis is $^1/_3b(d^3 - d_1^3)$.

Moment of Inertia of Compound Shapes. The moment of inertia of a compound shape about any axis equals the sum of the moments of inertia with reference to the same axis of all the rectangular portions composing it. It also equals the moment of inertia about a parallel axis through its center of gravity + (area of section × square of distance between axes). From this, the moments of inertia or radii of gyration of any single section being known, values may be found for any combination of these sections.

Table 2. Principal Radii of Gyration and Squares of Radii of Gyration

Surface or Solid	Radius of Gyration	Square of Radius of Gyration
Parallelogram: height h, axis at its base	$0.5773h$	$\frac{1}{3}h^2$
Parallelogram: height h, axis mid-height	$0.2886h$	$\frac{1}{12}h^2$
Straight rod: length l, or thin rectangular plate, axis at end	$0.5773l$	$\frac{1}{3}l^2$
Straight rod: length l, or thin rectangular plate, axis mid-length	$0.2886l$	$\frac{1}{12}l^2$
Rectangular prism: axes $2a$, $2b$, $2c$, referred to axis $2a$	$0.577\sqrt{b^2 + c^2}$	$(b^2 + c^2) \div 3$
Parallelopiped: length l, base b, axis at one end, at mid-breadth	$0.289\sqrt{4l^2 + b^2}$	$\dfrac{4l^2 + b^2}{12}$
Hollow square tube:		
Outer side h, inner h', axis mid-length	$0.289\sqrt{h^2 + h'^2}$	$(h^2 + h'^2) \div 12$
Very thin, side = h, axis mid-length	$0.408h$	$h^2 \div 6$
Thin rectangular tube: sides b, h, axis mid-length	$0.289\sqrt{\dfrac{h + 3b}{h + b}}$	$\dfrac{h^2}{12} \cdot \dfrac{h + 3b}{h + b}$
Thin circular plate: radius r, diameter h, axis on diameter	$\frac{1}{2}r$	$\frac{1}{4}r^2 = h^2 \div 16$
Flat circular ring: diameters h, h', axis on diameter	$\frac{1}{4}\sqrt{h^2 + h'^2}$	$(h^2 + h'^2) \div 16$
Solid circular cylinder: length l, axis on diameter at mid-length	$0.289\sqrt{l^2 + 3r^2}$	$\dfrac{l^2}{12} + \dfrac{r^2}{4}$
Circular plate: solid wheel of uniform thickness, or cylinder of any length, referred to axis of cylinder	$0.7071r$	$\frac{1}{2}r^2$
Hollow circular cylinder, or flat ring: l, length; R, r, outer and inner radii. Axis: 1, longitudinal axis; 2, diameter at mid-length	$0.7071\sqrt{R^2 + r^2}$ $0.289\sqrt{l^2 + 3(R^2 + r^2)}$	$(R^2 + r^2) \div 2$ $\dfrac{l^2}{12} + \dfrac{R^2 + r^2}{4}$
Same: very thin, axis its diameter	$0.289\sqrt{l^2 + 6R^2}$	$\dfrac{l^2}{12} + \dfrac{R^2}{2}$
Same: radius r; axis, longitudinal axis	r	r^2
Circumference of circle, axis its center	r	r^2
Circumference of circle, axis its diameter	$0.7071r$	$\frac{1}{2}r^2$
Sphere: radius r, axis its diameter	$0.6325r$	$\frac{2}{5}r^2$
Spheroid: equatorial radius r, revolving polar axis a	$0.6325r$	$\frac{2}{5}r^2$
Paraboloid: r = radius of base, revolving on axis	$0.5773r$	$\frac{1}{3}r^2$
Ellipsoid: semi-axes a, b, c; revolving on axis $2a$	$0.4472\sqrt{b^2 + c^2}$	$\dfrac{b^2 + c^2}{5}$
Spherical shell: radii R, r, revolving on its diameter	$0.6325\sqrt{\dfrac{R^5 - r^5}{R^3 - r^3}}$	$\dfrac{2}{5}\left(\dfrac{R^5 - r^5}{R^3 - r^3}\right)$
Same: very thin, radius r	$0.8165r$	$\frac{2}{3}r^2$
Solid cone: r = radius of base, revolving on axis	$0.5477r$	$0.3r^2$

9. CENTER AND RADIUS OF GYRATION

THE CENTER OF GYRATION with reference to an axis is that point at which the entire weight of a body may be concentrated without changing its moment of inertia. In a revolving body, it is the point at which the whole weight of the body may be conceived to be concentrated.

RADIUS OF GYRATION is the distance from the axis to the center of gyration. Let W = weight of the body; I = its moment of inertia; k = its radius of gyration. Then $I = Wk^2 = \Sigma wr^2$; $k = \sqrt{I/W} = \sqrt{\Sigma wr^2/W}$. The radius of gyration is least when the axis passes through the center of gravity, and is then known as the principal radius of gyration. Let k = principal radius of gyration; k' = any other radius of gyration; d = distance between the axes of k and k'. Then $k' = \sqrt{k^2 + d^2}$. Table 2 gives principal radii of gyration of the more common areas and solids, except structural shapes for which see Eshbach, *Handbook of Engineering Fundamentals*, Section 1. For radius of gyration of sections see pp. 8-09 and 8-10, this volume.

10. VELOCITY AND ACCELERATION

VELOCITY is the rate of motion, or speed of a body at any instant. If s = space, feet, passed over in t sec, and v = velocity, feet per second, when v is uniform, $s = vt$; $v = s/t$. If v varies uniformly, the mean velocity $v_m = \frac{1}{2}(v_1 + v_2)$, where v_1 and v_2 are the velocities at beginning and end of time t, respectively. $s = \frac{1}{2}(v_1 + v_2)t$.

If the velocity varies, but not uniformly, v for a very short interval of time $= s/t$, or in the calculus, $v = ds/dt$.

ACCELERATION, a, is the change in velocity occurring in unit time. The unit of a is 1 ft per sec per sec. For uniformly accelerated motion, a is constant. $a = (v_2 - v_1)/t$; $v_2 = (v_1 + at)$; $v_1 = (v_2 - at)$; $t = (v_2 - v_1)/a$.

If the body starts from rest, $v_1 = 0$, and the mean velocity $v_m = v_2/2$; $v_2 = 2v_m$; $a = v_2/t$; $v_2 = at$; $v_2 - at = 0$; $t = v/a$.

For acceleration due to gravity, and of falling bodies, see p. 7-25.

Deceleration or Retarded Motion. If a body starts with a velocity v_1 and comes to rest, $v_2 = 0$, and $s = {}^1/_2 v_1 t$. In any case, if the change in velocity is v, $s = {}^1/_2\, vt = v^2/2a = {}^1/_2\, at^2$.

For a body starting from or ending at rest, $v = at$; $s = {}^1/_2\, vt = {}^1/_2\, at^2$; $v^2 = 2as$.

CURVES OF VELOCITY AND ACCELERATION. If the velocity or acceleration are not uniform, or are represented by complex equations, they may be studied by plotting space, velocity, or acceleration against time. In Fig. 2, the space passed over is plotted as ordinates with seconds of time as abscissas. The angle made by the tangent to the curve at any point determines the velocity at that instant. Thus, the tangent BC at point A intersects the axis of abscissas at C and the velocity at A is $(AD/CD) = {}^3/_2$ ft per sec. Since the slope of the tangent is upward, the velocity is increasing, i.e., the point under consideration is being accelerated. The slope of tangent at F is downward, and hence the motion of the point is being retarded. If the curve at any point is parallel to the axis of abscissas, the motion is uniform.

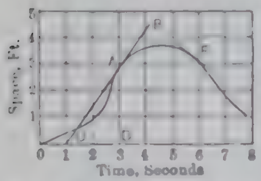

FIG. 2. Displacement-time diagram.

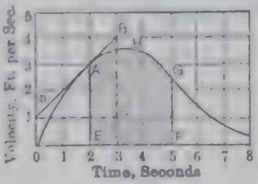

FIG. 3. Velocity-time diagram.

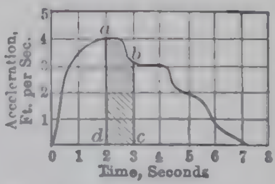

FIG. 4. Acceleration-time diagram.

In Fig. 3, velocity is plotted as ordinates and time as abscissas. The angle of the tangent to the curve at any point represents the acceleration at that instant. The acceleration at A is $(BC/CD) = {}^3/_3 = 1$ ft per sec per sec. As before, an upward slope represents acceleration, while a downward slope represents retardation or deceleration. The area under the curve between any two ordinates represents the space passed over in that interval of time. Thus area $AEFGH$ = 10 ft.

In Fig. 4, acceleration is plotted as ordinates and time as abscissas. The angle of the tangent to the curve at any point represents the velocity at that instant, and the area under the curve between two ordinates ad and bc represents the change in velocity during the interval.

For *uniform motion* the space-time curve is a straight line, inclined to the axis of abscissas, and the velocity-time curve is a straight line parallel to the axis of abscissas.

For *constant acceleration* or *constant retardation* the space-time curve is a parabola, and the velocity-time curve is a straight line, inclined away from or toward the axis of abscissas, depending upon whether the velocity increases or decreases. The acceleration-time curve is a straight line, parallel to the axis of abscissas.

ANGULAR VELOCITY is the time rate of turning of a body about an axis, or the angle through which any radius of a body turns in one unit of time. The unit of angular velocity is any unit of angular displacement per any unit of time, as revolutions per minute, revolutions per second, radians per minute, and radians per second. One *radian* $= 180/\pi$ degrees = 57.3 degrees. One rpm $= {}^1/_{60}$ rps $= 2\pi$ radians per min $= \pi/30$ radians per sec.

LINEAR VELOCITY OF A POINT ON A TURNING BODY is the product of the angular velocity of the body in radians per unit time and the distance from the axis of rotation to the point. If ω = angular velocity, radians per second; R = distance from axis of rotation to point, feet; N = angular velocity, revolutions per minute; and V = linear velocity of the point, feet per second, then $V = \omega R = 2\pi NR/60$. If V is in feet per minute, then $V = 60\omega R = 2\pi NR$. The linear velocity of a point in a revolving body is proportional to its distance from the axis of rotation.

ANGULAR ACCELERATION is the time rate of change of the angular velocity. The most commonly used unit of angular acceleration is radians per second per second.

LINEAR ACCELERATION OF A POINT ON A TURNING BODY is the resultant of two components, the normal acceleration and the tangential acceleration of the point. The normal acceleration is in feet per second per second, $A^n = \omega^2 R$, and the tangential acceleration is in feet per second per second, $A^t = \alpha R$, where ω and R are as defined above and α is angular acceleration in radians per second per second. The resultant linear acceleration of the point in feet per second per second is $A = \sqrt{(A^n)^2 + (A^t)^2}$.

11. FORCE, WORK, AND ENERGY

UNIFORMLY ACCELERATED MOTION. Let f be a constant force, acting for t sec on a body, at rest at the beginning of the time, but free to move without friction, the weight of the body being w lb. The body will move at a gradually increasing velocity v, which varies as ft/w.

If v is in feet per second, f in standard pounds of force,* t in seconds, and w in pounds, the equations that govern the motion of the body are as follows.

Let K = a constant derived by experiment. Then $v = Kft/w$. The value of K at sea level at latitude 45 degrees is 32.1740, and is twice the distance that a body *in vacuo* would fall in 1 sec. It usually is designated as g, commonly called acceleration due to gravity. The fundamental equation then is

$$v = \frac{ftg}{w} \tag{1}$$

Let S = distance through which the body moves. If v varies directly as time (uniformly accelerated motion), then $S = v_m t$, where v_m = mean velocity during time t. If v_0 = initial velocity and v = final velocity at end of time t, $v_m = (v_0 + v)/2$. For a body starting from rest $v_0 = 0$, and $v_m = v/2$. Hence, $S = {}^1/_2\, vt$; $v = 2S/t$; $t = 2S/v$. Substituting $v = 2S/t$ in eq. 27,

$$S = \frac{ft^2g}{2w} \tag{2}$$

If $f = w$, which is true of a falling body at latitude 45 degrees at sea level, eq. 1 becomes $v = gt$. Substitute in this equation $t = S/v$; then

$$v = \frac{2gS}{v} \quad \text{and} \quad v = \sqrt{2gS} \tag{3}$$

In eq. 2, put $f = w$. Then $S = {}^1/_2\, gt^2$.

From eq. 1, by transposition,

$$ft = w\frac{v}{g} = v\frac{w}{g} \tag{4}$$

w/g, the mass of the body frequently is designated as m, whence eq. 4 becomes

$$ft = mv \tag{5}$$

Substitute in eq. 4, $t = 2S/v$. Then $f2S/v = v \times w/g$, whence

$$fS = {}^1/_2\, mv^2 \tag{6}$$

By definition acceleration $a = v/t$, whence, from eq. 5,

$$f = ma\,\dagger \tag{7}$$

If two forces f, f_1, act on a body at different times, producing accelerations a, a_1, then $f = ma$ and $f_1 = ma_1$, whence

$$\frac{f}{f_1} = \frac{a}{a_1} \tag{8}$$

The foregoing eight equations and their transformations will solve all problems of uniformly accelerated motion.

---

* The pound avoirdupois is the unit of force used by American and British engineers. It is the force with which gravity attracts 1 lb of matter at sea level at 45 degrees latitude, and which would give to 1 lb of matter an acceleration of 32.1740 ft per sec per sec.

In the centimeter-gram-second system, the unit of force is the *dyne*. It is that force which acting on a mass of 1 gram will produce in 1 sec a velocity of 1 cm per sec.

† Eq. 7 sometimes is read "force equals mass times acceleration," which is strictly true in the dyne-centimeter-gram-second, or "absolute" system of measurements, in which force is measured in dynes, but it is not true in the pound-foot-second system, unless it is understood that the word "mass" means the quotient of W divided by g, the unit of which is known as the "slug." A slug is a mass which requires a force of 1 lb to give it an acceleration of 1 ft per sec per sec. At sea level, at latitude 45 degrees, a slug weighs 32.1740 lb.

FORCE OF ACCELERATION. To produce an acceleration of g (i.e., 32.174 ft per sec per sec), force required, $f = mg = (w/g)g = w$, or the weight of the body. Since $f = ma$, $f = m(v_2 - v_1)/t$, where v_2 and v_1 = respectively, initial and final velocities at beginning and end of time t. Also $f = mg = (w/g)/[(v_2 - v_1)/t] = (w/g)a$; $f/w = a/g$. In problems where the local attraction of gravity is a factor, the local value of g must be used if accuracy is necessary.

Example. Required the tension in a cord lifting 100 lb vertically through 80 ft, at velocity uniformly increasing from 0 to 40 at the end of 4 sec. Local value of g = 0.998 × standard value = 32.108; $v_m = 20$; final velocity $v_2 = 2v_m = 40$. Acceleration $a = v_2/t = 10$. Force required to produce acceleration $= f_a = ma = wa/g = (100 \times 10)/32.174 = 31.08$ lb. The standard value of g(32.174) is used here, since force required for acceleration is independent of gravity. Force required to lift the weight without acceleration $= f_w = 100 \times 0.998 = 99.8$ lb. The factor 0.998 is used in this equation because the force of gravity in the given locality is less than standard. Total tension in cord $= f_a + f_w = 130.88$ lb.

Resistance to acceleration equals the force necessary to produce acceleration $= (w/g)[(v_2 - v_1)/t]$.

FORMULAS FOR ACCELERATED MOTION. For cases of uniformly accelerated motion, other than those of falling bodies, we have the formulas already given, $f = (w/g)a$; $f = (w/g)[(v_2 - v_1)/t]$. If the body starts from rest, $v_1 = 0$, $v_2 = v$, and $f = (w/g)(v/t)$; $fgt = wv$. We also have $S = \frac{1}{2}vt$. Transforming and substituting 32.174 for g,

$$f = \frac{wv^2}{64.35S} = \frac{wv}{32.17t} = \frac{wS}{16.09t^2} \tag{9}$$

$$w = \frac{32.17ft}{v} = \frac{64.35fS}{v^2} \tag{10}$$

$$S = \frac{wv^2}{64.35f} = \frac{16.09ft^2}{w} = \frac{vt}{2} \tag{11}$$

$$v = 8.02\sqrt{\frac{fS}{w}} = \frac{32.17ft}{w} \tag{12}$$

$$t = \frac{wv}{32.17f} = \frac{1}{4.01}\sqrt{\frac{wS}{f}} \tag{13}$$

For varying velocity,

$$f = w\frac{v_2^2 - v_1^2}{64.35S} \tag{14}$$

WORK OF ACCELERATION. The work P done in accelerating a body is $f \times S$, where f = force producing acceleration and S = distance covered in time t. The force, $f = ma = (w/g)[(v_2 - v_1)/t]$, and

$$P = \frac{w}{g}\frac{v_2 - v_1}{t}S \tag{15}$$

Example. Work required to move horizontally 80 ft in 4 sec a frictionless body weighing 100 lb, at uniformly increasing velocity. Mean velocity, $v_m = 20$; initial velocity $v_1 = 0$; final velocity $v_2 = 2v_m = 40$; $a = (v_2 - v_1)t = 40/4 = 10$; $f = (w/g)a = (100/32.16) \times 10 = 31.1$ lb; $S = 80$; $P = fS = 31.1 \times 80 = 2488$ ft-lb. Energy stored in the body at the final velocity $v = 40$, equals the work of acceleration.

$$E = \frac{1}{2}mv^2 = \frac{1}{2}\frac{w}{g}v^2 = \frac{100 \times 40^2}{2 \times 32.16} = 2488 \text{ ft-lb}$$

WORK OF ACCELERATED ROTATION. Let ω = angular velocity, radians per second, of a particle of weight w, rotating at unit radius r around an axis. The velocity $v_1 = \omega_1 r$. If angular velocity is accelerated to ω_2, velocity of particle becomes v_2. Increase in velocity is $(v_2 - v_1) = r(\omega_2 - \omega_1)$, and the work of acceleration is

$$P_a \frac{w}{g}\frac{v_2^2 - v_1^2}{2} = \frac{wr^2}{g}\frac{\omega_2^2 - \omega_1^2}{2} \tag{16}$$

The work of a rotating body around an axis is

$$\Sigma\frac{\omega}{g} \times \frac{1}{2}(v_2^2 - v_1^2) = \frac{\omega_2^2 - \omega_1^2}{2g \times \Sigma wr^2} \tag{17}$$

where Σwr^2 = moment of inertia of the body.

MEASURE OF ENERGY in a body is the product of its weight and the height from which it must fall to acquire actual velocity. If v = velocity, feet per second, h = height, feet, corresponding to velocity $= v^2/2g$ (see Falling Bodies below), and if w = weight, pounds, energy, foot-pounds, $E = {}^1/_2\, mv^2 = wv^2/2g = wh$. Since energy is the capacity for doing work, the units of work and energy are equivalent, or $FS = {}^1/_2\, mv^2 = wh$.

In a rotating body, $E = \omega^2 I/2g$, where ω = angular velocity, radians per second and I = moment of inertia, in pound-feet.[2] Also, $E = wv^2/2g$, where v = velocity of center of gyration.

THE LAW OF GRAVITATION states that two bodies attract each other with a force directly proportional to their masses and inversely proportional to the square of the distance between them. Let F = force with which two bodies of masses m_1 and m_2 attract each other and d = distance between them. Then $F = Cm_1m_2/d^2 = C(w_1/g)(w_2/g)/d^2 = Cw_1w_2/d^2g^2$, where C = gravitation constant of two spheres of unit mass, i.e., the force with which they attract each other through unit distance. $C = 3.31 \times 10^{-11}$ if F, w, and d are in pounds and feet.

MOMENTUM. IMPULSE. Momentum is the product of the mass and velocity of a body, i.e., momentum $= mv = (w/g)v$. In eq. 5, $ft = mv$; the expression ft is sometimes termed the impulse, whence Impulse = Momentum.

FALLING BODIES. The formulas for falling bodies are derived from eqs. 9 to 14 by putting $f = w$. If g be taken as 32.16 (value at 40 degrees latitude), v = velocity, feet per second, at end of time t; h = height of fall, feet, then

$$v = gt = 32.16t = \sqrt{2gh} = 8.02\sqrt{h} = \frac{2h}{t} \tag{18}$$

$$h = \frac{gt^2}{2} = 16.08t^2 = \frac{v^2}{2g} = \frac{v^2}{64.32} = \frac{vt}{2} \tag{19}$$

$$t = \frac{v}{g} = \frac{v}{32.16} = \sqrt{\frac{2h}{g}} = \frac{\sqrt{h}}{4.01} = \frac{2h}{v} \tag{20}$$

u = space fallen through during Tth sec

$$= h_t - h_{t-1} = \frac{gt^2}{2} - \frac{g(t-1)^2}{2} = \frac{g}{2}(2t-1) = g(t - {}^1/_2) \tag{21}$$

Solving the above equations, the values of v, h, t, u, are:

$t =$	1	2	3	4	5	6	7	8	9	10
$g = 32.16 \times$	1	1	1	1	1	1	1	1	1	1
$v = 32.16 \times$	1	2	3	4	5	6	7	8	9	10
$u = (32.16/2) \times$	1	3	5	7	9	11	13	15	17	19
$h = (32.16/2) \times$	1	4	9	16	25	36	49	64	81	100

Value of g increases with latitude and decreases with elevation above sea level. At Philadelphia, latitude 40 degrees, $g = 32.16$. Everett's formula for g is

$$g = 32.173 - 0.082 \cos (2 \times \text{latitude}) - 0.000003 \text{ height in ft} \tag{22}$$

The standard value of g at latitude 45 degrees given by International Conference on Weights and Measures, Paris, 1901, is 32.1740. The value of $\sqrt{2g}$ decreases about 0.0004 per 1000-ft elevation above sea level. For all ordinary calculations in the United States, $g = 32.16$ and $\sqrt{2g} = 8.02$. In England, $g = 32.2$; $\sqrt{2g} = 8.025$. C. S. Pierce gives limiting values in the United States as: at latitude 49 degrees, at sea level, $g = 32.186$; at latitude 25 degrees, 10,000 ft above sea level, $g = 32.089$.

Local values of g are used in calculations involving local gravitational force, as falling bodies, lifting weights, and water powers. In all cases involving the expression w/g, the standard value, $g = 32.1740$ should be used.

CENTRIFUGAL FORCE. A body revolving in a curved path of radius $= R$ ft exerts a force, called centrifugal force, on the arm or cord that restrains it from moving in a straight line. If W = weight of body, pounds; N = revolutions per minute; v = linear velocity of center of gravity of body, feet per second; $g = 32.174$,

$$v = \frac{2\pi RN}{60} \tag{23}$$

$$F = \frac{Wv^2}{gR} = \frac{Wv^2}{32.174R} = \frac{W4\pi^2RN^2}{3600g} = \frac{WRN^2}{2933.9} = 0.00034084WRN^2 \text{ lb} \tag{24}$$

If n = revolutions per second, $F = 1.2270WRn^2$.

The force that restrains the body from moving in a straight line, i.e., the tension in the cord or arm, is called *centripetal force*, and is equal to and opposite to the centrifugal force.

12. OSCILLATION AND PERCUSSION

CENTER OF OSCILLATION. A body oscillates about a fixed axis, outside its center of gravity. The center of oscillation is a point on the line drawn from the center of gravity of the body, perpendicular to the axis, whose motion is the same as it would be were the entire mass of the body there concentrated and allowed to vibrate as a pendulum.

RADIUS OF OSCILLATION is distance from center of oscillation to point of suspension $= r = R^2/l$. R = radius of gyration, l = distance from point of suspension to center of gravity. Centers of suspension and oscillation are mutually convertible. The center of oscillation of a straight line, or uniform thin bar or cylinder of length L suspended from and oscillating about one end, is $^2/_3\ L$ from the axis. If the point of suspension is $^1/_3\ L$, the center of oscillation is again $^2/_3\ L$ from the axis, i.e., at end of bar. The time of oscillation t is the same in both cases. If point of suspension is at center of gravity, in the simple equivalent pendulum $L = \infty$ and $t = \infty$.

A sphere of radius R is suspended by a cord. Let h = distance of axis of motion to center of sphere, h' = distance of center of oscillation to center of sphere, r = radius of oscillation $= h + h' = h + {}^2/_5\,(R^2/h)$. If the sphere oscillates about an axis tangent to the surface $h = R$ and $r = R + {}^2/_5\,R$.

For various plane figures the length of radius of oscillation is given in Table 3.

Table 3. Length of Radius of Oscillation of Plane Figures

Figure	Direction of Vibrations Perpendicular to Plane of Figure	 In Plane of Figure
Isosceles triangle	$^3/_4$ altitude	
Circle	$^5/_8$ diameter	$^3/_4$ height
Parabola	$^5/_7$ height	$^5/_7$ height + $^1/_3$ parameter * $^4/_7$ height + $^1/_2$ parameter †
Rectangle		$^2/_3$ diagonal ‡

* Suspended by vertex. † Suspended by middle of base. ‡ Suspended by one angle.

THE PENDULUM. The *simple pendulum* is an ideal body concentrated at the center of oscillation, suspended from a fixed point by a weightless string. A *compound pendulum* is a body of any form suspended from a fixed axis about which it oscillates by force of gravity. The equivalent simple pendulum has the same weight and the same moment of inertia referred to an axis through point of suspension, and it vibrates in the same time. The ordinary pendulum of given length vibrates in equal times when the angle of vibration does not exceed 2 degrees or 2 $^1/_2$ degrees on each side of the vertical. This property is *isochronism.*

Let T = time of vibration, seconds, l = length of simple pendulum, g = acceleration due to gravity, which is constant at a given locality. $T = \pi\sqrt{l/g}$; since π = constant, $T \propto \sqrt{l/g}$, and in a given locality $T \propto \sqrt{l}$. If l = constant, then for any locality $T \propto \sqrt{g}$.

If T = constant, $gT^2 = \pi^2 l$; $l \propto g$, $g = \pi^2 l/T^2$. This equation gives the force of gravity at any locality if l of a simple pendulum vibrating seconds at that locality is known. At New York, $l = 39.1017$ in. $= 3.2585$ ft, and $g = 32.16$ ft. The time of vibration of any pendulum at New York $= T\sqrt{l/39.1017} = 0.16\sqrt{l}$. The length of a pendulum at New York, having a given time of vibration is $l = T^2 \times 39.1017$ in.

The time of vibration may be varied by adding a weight or *bob* above the point of suspension, which lengthens time T. By varying the height of the upper bob, T is varied.

Let W, w = weight of lower and upper bobs, pounds, respectively; D, d = distance, inches, of lower and upper bobs, respectively, from point of suspension. Then $w = W[(39.1D - D^2)/(39.1d - d^2)]$. Thus by adding a second bob, short pendulums may be made to vibrate as slowly as long ones.

Conical Pendulum. A weight suspended by a cord and revolving at a uniform speed in the circumference of a circular horizontal plane whose radius is r, the distance of the plane below the point of suspension being h, is held in equilibrium by three forces—the tension in the cord, the centrifugal force, which tends to increase the radius r, and the force of gravity acting downward. If v = velocity, feet per second of the center of gravity of the weight, as it describes the circumference, $g = 32.16$, and r and h are taken in feet, the time in seconds of performing one revolution is (at New York or other place where $g = 32.16$)

$$t = \frac{2\pi r}{v} = 2\pi\sqrt{\frac{h}{g}} \qquad h = \frac{gt^2}{4\pi^2} = 0.8146t^2$$

If $t = 1$ sec, $h = 0.8146$ ft $= 9.775$ in.

CENTER OF PERCUSSION is identical with center of oscillation and is the point at which the percussive action of a blow is the same as if the whole mass of the body were concentrated at the point.

IMPACT. Let m_1, m_2 = mass of two inelastic bodies; v_1, v_2 = their respective velocities. Then if these two bodies collide, they will move on as one mass with a common velocity v. $(m_1 + m_2)v = m_1v_1 + m_2v_2$, and $v = (m_1v_1 + m_2v_2)/(m_1 + m_2)$. If the bodies move in opposite directions, $v = (m_1v_1 - m_2v_2)/(m_1 + m_2)$. If $m_1v_1 = m_2 v_2$ and the bodies impinge directly from opposite directions, $v = 0$; that is, the bodies will be brought to rest.

The loss of energy resulting from the impact of inelastic bodies is the sum of the energies lost and gained by the bodies respectively.

$$1/2\, m_1v_1^2 + 1/2\, m_2v_2^2 - 1/2\,(m_1 + m_2)v_2 = 1/2\, m_1(v_1 - v)^2 + 1/2\, m_2(v_2 - v)^2$$

EXAMPLE. Let $m_1 = 10$, $m_2 = 8$, $v_1 = 12$, $v_2 = 15$. $v = [(10 \times 12) - (8 \times 15)]/(10 + 8) = 0$.

$$\text{Energy loss} = (1/2 \times 10 \times 12^2) + (1/2 \times 8 \times 15^2)$$
$$= [1/2 \times 10 \times (12 - 0)^2] + [1/2 \times 8 \times (15 - 0)^2] = 1620 \text{ ft-lb}$$

The lost energy does internal work on the bodies by changing their shape and heating them.

For imperfectly elastic bodies of elasticity $e = f_r/f_c$,

$$v_1' = \frac{m_1v_1 + m_2v_2}{m_1 + m_2} - \frac{m_2e(v_1 - v_2)}{m_1 + m_2} \qquad v_2' = \frac{m_1v_1 + m_2v_2}{m_1 + m_2} + \frac{m_2e(v_1 - v_2)}{m_1 + m_2}$$

where v_1' and v_2' = respective velocities of the bodies after impact, f_r = internal force tending to restore shape of body after compression, f_c = force of compression, other notation being as before.

For perfectly elastic bodies, $v_1' - v_2' = v_2 - v_1$; that is, relative velocities before and after impact are the same, and $m_1v_1' + m_2v_2' = m_1v_1 + m_2v_2$.

13. FRICTION

FRICTION may be defined as the resisting force tangent to the surfaces of two bodies when one body moves or tends to move upon the other. The magnitude of the frictional force depends upon the force with which the bodies are pressed together. Friction may be either useful or harmful. In brakes, clutches, belts, bolted or riveted joints, and self-locking mechanisms, friction is useful. Friction is harmful in bearings, gears, and flow of fluids. If the resistance between two bodies prevents relative motion, the resistance is called friction of rest or static friction. When there is relative motion between the bodies, the resistance is called friction of motion or kinetic friction. Static friction increases until motion impends. Kinetic friction, except at very low velocities, is less than static friction when motion just impends. For a discussion of the principles and laws of friction see *Handbook of Engineering Fundamentals* by Eshbach (John Wiley and Sons).

COEFFICIENT OF FRICTION. The ratio of the force required to slide a body along a horizontal plane surface to the weight of the body is called the coefficient of friction. It is equivalent to the tangent of the *angle of repose*, which is the angle of inclination, to the horizontal, of an inclined plane on which the body will just overcome its tendency to slide. The angle usually is denoted by θ, and the coefficient by f or λ. $f = \tan \theta$. If the inclined surface (Fig. 5a) upon which a loaded block rests without motion is made gradually steeper until the block starts to slide, the angle at which the sliding starts is the angle of repose for static friction. After the motion has begun, if the angle is not reduced, the block usually will accelerate down the incline. If the angle is then reduced until the block slides with uniform velocity, the angle at which this occurs may be used to determine the friction opposing that particular velocity. The angle Δ shown in Fig. 5b is used as a measure of the manner in which granular materials may be heaped. This angle varies widely with the nature of the material. Values of f for a wide variety of materials, both at rest and in motion, are given in Table 4. In Fig. 5a, F = frictional resistance = fN, where N is force normal to plane or force pressing two bodies together, = $R \cos \theta$, where R is weight of body.

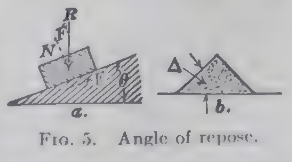

FIG. 5. Angle of repose.

Starting Friction of Newly Finished Bearing Surfaces. The next three paragraphs* summarize tests at Kingsbury Machine Works of newly finished surfaces to determine influence of method of finishing on

---

the coefficient of starting friction in the absence of vibration. The tests were made with a babbitt-faced shoe, of 60.7 sq in. area, scraped to a surface plate, opposed to a close-grained cast-iron surface, finish turned and lapped with fairly coarse silicon carbide. The surfaces were immersed in light oil, and subjected to a load of over 300 psi for several hours. The coefficient of starting friction was as high as 0.66. It was reduced to as low as 0.21 by more refined finishes. The lowest coefficients were found when the cast-iron surfaces had been scrubbed by rotation, pressed by a leather-covered block, using lubricating oil impregnated with a very fine abrasive. The direction of motion during test (so long as it is concentric) seems to have little influence on the coefficient of friction.

Some of the values of starting coefficient of friction determined were: lard oil, load applied for 2 hr, $f = 0.18$; castor oil, load applied for 113 hr, $f = 0.25$; light mineral oil, viscosity 150 Saybolt universal seconds, load applied 14 to 18 hr, $f = 0.30$. Kerosene gave higher values than the mineral oil. The conclusions drawn from the test were: In the absence of vibration, the starting friction coefficient is a function of the newness of the surfaces, of the methods of finishing employed, of the time which the surfaces have been pressed together, of the pressure acting on them, of the nature and viscosity of the lubricating oil in which the surfaces are immersed, and of the area of the smaller of the two faces. When the surfaces are loaded to around 300 psi and have an area of 60 sq in., the coefficient of static friction in the absence of vibration may be expected to be below 0.30 for new faces, and below 0.20 for those in service. The influence of electrical vibration is believed to reduce these values 20% or more.

Influence of Surface Finish on Starting Friction and Friction at Low Speed. Howarth's experiments on a low speed and other tests of Kingsbury thrust bearings (*Trans. ASME*, xli, p. 685, 1919) show the variation, with speed and load, of friction of motion in a small thrust bearing of a mean diameter of 9.375 in., having four babbitt-faced shoes and a revolving cast-iron runner. The total shoe area was varied from 71.5 sq in. to 10 sq in. in order to test pressures ranging from 140 to 1000 psi. In a typical test, the load was 600 psi. Machine oil, of 5.345 Saybolt universal seconds viscosity at the test temperature, was used as lubricant, the surfaces being always submerged. The test was started at 16 rpm, speed being reduced gradually to 1/3 rpm. The friction coefficient increased gradually, but irregularly, from about 0.0015 at 16 rpm to about 0.132 at 1/3 rpm. The speed then was gradually increased without changing the load. The friction coefficients determined for the increasing speeds were much lower than that for decreasing speeds. This was explained by the improvement of bearing surfaces due to the long running at low speed. During these tests friction coefficients for starting from rest were found to vary from 0.15 to 0.20. These values, therefore, may be considered satisfactory for bearing surfaces that have been in operation for some time under favorable conditions in which a number of starts and stops have gradually brought the surfaces to a condition favorable to such starting when immersed in an oil bath.

Maximum Friction. When two metals are sweated or brazed together, the force required to separate them transversely at the joint is less a function of the pressure than of the transverse shearing strength of the metal bond. This might be a combination of the breaking of the bond between the soft and hard material and the actual shearing of the soft material on itself. The force required for such separation cannot be expressed consistently by means of a coefficient of friction.

INTERLOCKING FRICTION. If two surfaces interlock, as in a square thread screw (Fig. 6*a*), the force required to slide one on the other depends more on strength of the materials and proportion of interlocking than on the load acting between them. If the surfaces are free to move vertically against a load (Fig. 6*b*), the force required to slide them laterally would be a combination of sliding friction and lifting of the load. When an irregular hard surface presses against a soft one (Fig. 6*c*), the resistance offered to sliding one over the other will depend on the normal load, on the sliding friction, on resistance to deformation of the soft surface, and on the strength of the softer surface as it might be broken down because of interlocking. Figure 6*d* illustrates abrading frictional resistance to sliding of one surface over another, as a saw or file. The greater the normal pressure on the saw or file, the more will it cut into the lower block and the greater will be the resistance offered to transverse motion.

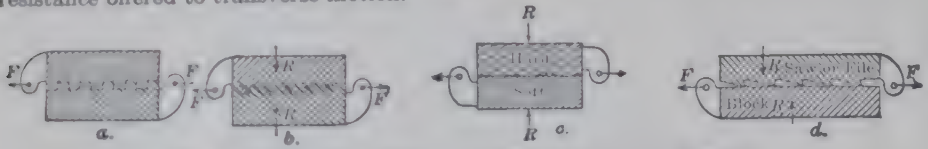

FIG. 6. Interlocking friction. (Courtesy of H. A. S. Howarth)

INFLUENCE OF VIBRATION. Tests to determine starting friction show coefficients of friction to be much higher in the absence of vibration than in its presence, and that friction decreases as the disturbance by vibration increases. Vibration similarly reduces the friction of motion so long as metallic contact is present in any considerable degree. With perfect lubrication, bearing surfaces are completely separated by lubricating films, and vibration does not appear to change the coefficient of friction of motion.

ROLLING FRICTION is the force required to roll a cylindrical or spherical body on a plane or on a curved surface. It depends on the nature of the surfaces and on the force with which they are pressed together, but is different from ordinary, or sliding, friction.

Rolling friction is a consequence of the irregularities of form and the roughness of surface of bodies rolling one over the other. Its laws are not yet definitely established in consequence of the uncertainty which exists in experiment as to how much of the resistance is due to roughness of surface, how much to original and permanent irregularity of form, and how much to distortion under the load.

Coefficients of Rolling Friction. Let R = resistance applied at the circumference of the wheel, W = total weight, r = radius of the wheel, and f = a coefficient which is a linear quantity expressed in the same units as r. Then $R = fW \div r$. The value of f is very variable. Probable values of f (in inches) based upon values given by Coulomb, Goodman, Pambour, and Weisbach are as follows:

Lignum vitae on oak	0.02
Elm on oak	0.032
Soft wood rollers on wood	0.06
Cast iron on cast iron	0.018
Cast iron or steel on steel	0.007 to 0.02
Cast iron or steel on wood	0.06 to 0.1
Cast iron or steel on macadam	0.05 to 0.2
Cast iron or steel on granite	0.085

The friction of pneumatic tires on roads is discussed in Kent's *Mechanical Engineers' Handbook—Power*, Section 14.

GRANULAR FRICTION. The friction required to move one surface over another when granular material is placed between them probably is a combination of several kinds of interaction. The simplest condition is that in which the granular particles turn over and over without interference (Fig. 7*a*). Figure 7*b* indicates how the granular particles may become interlocked so that they will abrade each other and may cut both surfaces when motion occurs. Figure 7*c* represents granular particles embedded in the softer surface and acting as cutters when moved on the harder surface.

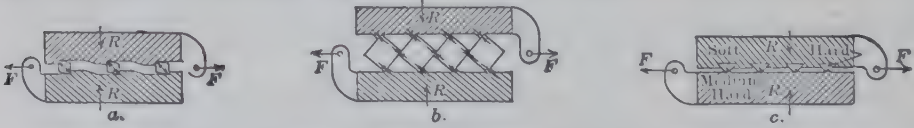

FIG. 7. Granular friction. (Courtesy of H. A. S. Howarth)

SKIDDING FRICTION results from slipping of rubber tires on a pavement. The friction depends on the type of tire surface and conditions of the pavement. With rough pavement and smooth tires, high spots on the pavement will penetrate any film that is formed and project into the rubber, thus diminishing tendency to skid. With a smooth pavement and tires, the film of water, clay, or pulpy material found on roads will completely separate the surfaces. The tire then will slide freely in any direction. The coefficient of friction of rubber tires on roads depends upon the condition of the road and the tire tread, speed, and inflation of tire. Values commonly used are $f = 0.7$ for dry asphalt, $f = 0.8$ for wet asphalt, and $f = 0.1$ for soft, slippery roads.

FLUID FRICTION includes the frictional resistance to motion of fluids in containers, as the flow of water or gas in pipes; of solid bodies completely separated by a film of fluid, as a perfectly lubricated bearing; of solids partially or wholly immersed in a fluid, as a boat moving through water. Thurston states that for all fluids, whether liquid or gaseous, the resistance is (1) independent of the pressure between the masses in contact; (2) directly proportional to the area of rubbing surface; (3) proportional to the square of the relative velocity at moderate and high speeds, and to the velocity nearly at low speeds; (4) independent of the nature of the surfaces of the solid against which the stream may flow, but dependent to some extent upon their degree of roughness; (5) proportional to the density of the fluid, and related in some way to its viscosity. Fluid friction, as related to the flow of liquids in pipes, is discussed in Kent's *Mechanical Engineers' Handbook—Power*, p. 6-35.

14. FRICTION IN MACHINE ELEMENTS

FRICTION OF BEARINGS. For a detailed discussion of the friction of bearings, see pp. 12-03 to 12-40. The following data, from various sources, are for general guidance only. For design, in cases where friction is an important factor, reference should be made to the pages cited.

FRICTION OF JOURNALS. The friction of journals usually is expressed in terms of units of projected area, that is, $d \times l$, where d = diameter and l = length of journal. Unwin states that the friction of journals must lie between $\pi fP/2$ and $4fP/\pi$, where f = coefficient of friction and P = load on journal. For journals in ordinary condition the value of fP usually is sufficiently accurate. Values of f vary according to different authorities. Unwin gives the following:

Authority	f	Conditions
Morin	0.05 –0.07	Good journals, well lubricated
Rühlmann and Waltjen	0.02 –0.03	Wrought-iron on gun metal
Kirchweger	0.009–0.01	Wrought-iron on white metal *
Kirchweger	0.014	Wrought-iron on gun metal *
Bokelberg and Welkner	0.0028	Small loads, low velocities †
Bokelberg and Welkner	0.013	Heavy loads, high velocities †

* Railway journals well lubricated.

† In these experiments f was less for gun metal than for white metal.

The work lost in friction in foot-pounds per minute, is $W = fP\pi n(d/12)$, where n = revolutions per minute, d = diameter of journal, inches, other notation as above.

The friction of a journal is influenced by the nature and quantity of lubrication.

Value of Antifriction Metals. According to Professor J. E. Denton the various white metals available for lining brasses do not afford coefficients of friction lower than can be obtained with bare brass, but they are less liable to "overheating," because of the superiority of such material over bronze in ability to permit of abrasion or crushing, without excessive increase of friction. Thurston says that gun bronze, babbitt, and other soft white alloys have substantially the same friction; in other words, the friction is determined by the nature of the unguent and not by that of the rubbing surfaces, when the latter are in good order. The soft metals run at higher temperatures than the bronze. This, however, does not necessarily indicate a serious defect, but simply defficient conductivity. The value of the white alloys for bearings lies mainly in their ready reduction to a smooth surface after any local or general injury by alteration of either surface of form. See Bearing Metals, pp. 4-73 to 4-78.

Ball Bearings. The friction of ball bearings varies with the design and construction of the bearing. In general, it decreases with increase of load and is independent of speed and temperature. Stribeck found the coefficient of friction in one type of bearing at 65 rpm to vary from $f = 0.0033$ with a load of 838 lb to $f = 0.0015$ with a load of 6614 lb. At 780 rpm the same bearings showed $f = 0.0037$ and $f = 0.0013$, respectively, at 838 lb and 6614 lb loads.

Goodman gives the following ranges for f in various types of ball bearings: cylindrical, 2-point bearing, $f = 0.0012$ to 0.0018; thrust, 2-point bearing, $f = 0.0008$ to 0.0012; thrust, 3-point bearing, $f = 0.0018$ (average); thrust, 4-point bearing, $f = 0.0055$.

Roller Bearings. The coefficient of friction of roller bearings decreases with increase of load and with increase of temperature. It seems to be independent of the speed. Goodman gives values at loads of 2000 and 10,000 lb respectively, of $f = 0.0131$ to 0.0072 for 40 rpm, and of $f = 0.0053$ to 0.0024 for 400 rpm.

GEARING. The friction of gearing depends on the type, the material of the gears, the quality of workmanship, the quality of lubrication, and the form of the teeth. Values given below should be used with caution, as they are applicable only under conditions identical with those under which the determination was made.

Spur Gears. Wilfred Lewis gives the following as the friction losses F of various types of spur gears, in which p = circular pitch; 20-degree stub gear, addendum of $0.24p$, $F < 1\%$; $22\ ^1/_2$-degree gear, addendum of $0.28p$, $F = 1\%$ approx.; $14\ ^1/_2$-degree gear, addendum of $0.32p$, $F = 1.3\%$ approx. Other investigators report friction losses of cut gears in the neighborhood of 1%. The length of addendum has greater effect on the friction than has the angle of obliquity.

Bevel Gears. Various investigators have reported friction losses ranging from 1% under exceptionally good conditions of workmanship and lubrication to 8.6% under less favorable conditions.

Helical Gears. Friction losses in helical gears are composed of the tooth friction losses, which correspond to those of spur gears, and the losses resulting from the transverse sliding of the teeth on each other. The ratio F_s of lost work, due to this latter cause, to the useful work may be expressed as

$$F_s = \frac{\sin \alpha(\beta + \theta)}{\sin \beta \sin (\alpha + \theta)} - 1$$

in which α and β are, respectively, the helical angles of the gears and θ is the angle of repose, determined from the coefficient of friction, i.e., $f = \tan \theta$.

Worm Gearing. Let β = lead angle of the worm, ϕ = pressure angle of the gear tooth, and f = coefficient of friction. Then

$$\text{Efficiency} = \frac{\tan \beta(\cos \phi - f \tan \beta)}{\cos \phi \tan \beta + f}$$

Inasmuch as the pressure angle ϕ is small, the cosine is almost unity ($\cos 14\ ^1/_2° = 0.96815$ and $\cos 20° = 0.93969$) and the efficiency is approximately

$$\text{Efficiency} = \frac{\tan \beta - f \tan^2 \beta}{\tan \beta + f}$$

With f and $\tan \beta$ small, the term $f \tan^2 \beta$ is practically zero, hence

$$\text{Efficiency} \doteq \frac{\tan \beta}{\tan \beta + f}$$

where $\tan \beta = np/2\pi r$; n = number of threads on worm; p = linear pitch of worm; and r = pitch radius of worm.

The coefficient of friction f depends upon the material, the surface finish, the lubrication, and the rubbing velocity. Its value usually ranges from 0.02 to 0.05 but may be as high as 0.15 with poor lubrication and rubbing velocities below 40 ft per min. For a case-hardened, ground, and polished steel worm, mating with a bronze gear and well lubricated, the coefficient of friction is approximately $f = 1.28/V^{0.6}$, where V = rubbing velocity in feet per minute.

FRICTION OF HYDRAULIC PLUNGER PACKING. Hütte (Ref. 1, p. 202) says: "For stuffing-boxes with hemp, cotton or leather packing, with water pressures between 1 and 50 atmospheres, the frictional loss depends on the water pressure, the circumference of the packed surface, and a coefficient μ, which is constant for this range of pressure. The loss is independent of the depth of stuffing-box or leather ring, and is given by the formula $F = Kpd$, where F = total frictional loss, pounds, p = pressure, pounds per square inch, d = diameter of plunger, inches." K, a coefficient which depends on the kind and condition of the packing, is given as follows for various cases:

For cotton or hemp, loose or braided, dipped in hot tallow, plungers smooth, glands not pulled down too tight, packing therefore retaining its elasticity, dimensions such as usually occur, $K = 0.072$.

Same conditions, after packing is some months old, $K = 0.132$.

Materials the same, but with hard packing, unfavorable conditions, etc., K = as much as 0.299.

Leather packing, soft leather, well made, etc., $K = 0.036$ to 0.084.

Hard, stiffly tanned leather, $K = 0.12$ to 0.156.

Unfavorable conditions, rough plungers, gritty water, etc., K = up to 0.239.

Weisbach-Hermann (Ref. 2) gives a formula which, when translated into the same notation as the one in Hütte, is

$$F = 0.0312pd \text{ to } 0.0767pd$$

Since the total pressure on a plunger is $^1/_4\,\pi d^2p$, the ratio of the loss of pressure to the total pressure is $Kpd/^1/_4\,\pi d^2p$, or using the extreme values of K, 0.0312 and 0.299, the ratio ranges from $0.04/d$ to $0.38/d$, or from 4 to 38% divided by the diameter in inches.

FRICTION OF KEYS AND COTTERS. In a taper key, the angle between the tapered sides of which is α, the force required to drive the key home is

$$F = P[\tan(\theta + \alpha) + \tan\theta]$$

where P = pressure on the key normal to one of the tapered sides and θ = angle of repose of the surfaces in contact.

The force required to drive the key out is

$$F_1 = P[\tan(\theta - \alpha) + \tan\theta]$$

The limiting value of α is 2θ, for if $\alpha > 2\theta$ the key will not remain in position. If $f = 0.08$, $\theta = 4.5$ degrees. The greatest angle of taper, therefore, is 9 degrees or a taper of approximately 1 in 7. Similarly for cotters, where α_1, and α_2, respectively, are the angles made by the two edges of the cotter with a center line normal to the line of pressure,

$$F = P[\tan(\theta + \alpha_1) + \tan(\theta + \alpha_2)]$$

and

$$F_1 = P[\tan(\theta - \alpha_1) + \tan(\theta - \alpha_2)]$$

As before, the cotter will slip out if $(\alpha_1 + \alpha_2) > 2\theta$, which gives a limiting value of $(\alpha_1 + \alpha_2) = 9$ degrees when $f = 0.08$.

FRICTION OF ROPE SHEAVES. Unwin gives $f = 0.28$ for rope on a metal pulley. With ropes in grooves whose sides make an angle of 45 degrees, the pressure between the rope and the sides of the groove is greater than the force pressing the rope into the groove, the ratio being $(\operatorname{cosec}\theta/2) : 1$, where θ = angle of inclination of groove. The actual coefficient of friction of a rope in a sheave groove then is

$$f = 0.28 \times \operatorname{cosec} {}^1/_2\,\theta$$

giving for a 45-degree groove $f = 0.7$.

FRICTION OF V-GUIDES. Let P be the force pressing a V-shaped block into V-guides, the angle between the faces of the guides being β. The frictional resistance R to the movement of the block along the guides will be

$$R = \frac{fP}{\sin {}^1/_2\,\beta}$$

where f = coefficient of friction between the metals of the guides and blocks.

FRICTION IN LINKAGES may be analyzed graphically by use of the *friction circle.* If friction is neglected, the line of action of the forces is considered to be normal to the contacting surfaces. If friction is considered, the line of action of the forces is tangent to the friction circle whose diameter is the product of the coefficient of friction and the journal diameter. Figure 8 is a line drawing to scale of a slider-crank mechanism with friction neglected. The piston C is the driver with an instantaneous force P. All forces act normal to the contacting forces. Figure 9 is the same mechanism with friction considered. The circles at the connections are the friction circles drawn to the same scale as the drawing. θ is the friction angle for sliding friction. The lines of action of the forces are drawn tangent to the friction circles and in such a direction that friction opposes the motion.

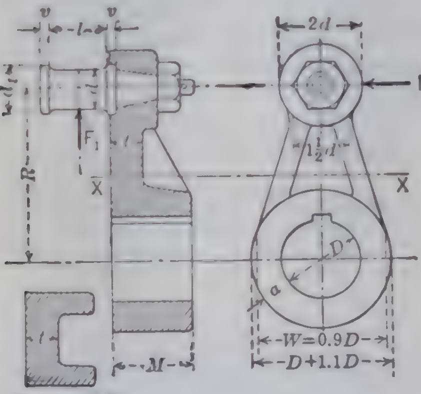
MACHINE ELEMENTS

15. CRANKS AND CRANKPINS

There are two types of cranks: the overhung or side crank (Figs. 1 and 2) and the center crank (Fig. 3). The proportions of each are different. In the side crank, the crankpin is a cantilever, in the center crank, the crankpin is a simple beam. The crankarm or web of a side crank must carry the same load as both arms of the center-crank type. The dimensions of the crankpin are determined by the bearing and lubrication requirements and then checked for strength and deflection. The proportions of the various parts are often empirical. Forged crankshafts are usually SAE 1020, SAE 1030, or SAE 2340 steel. Chrome-nickel steel, SAE 3140 and SAE 3240, are used in automobile and aircraft-engine crankshafts. Some of the special iron-copper alloys are also used in automobile crankshafts. Cast-iron cranks are used only in small inexpensive machinery; however, high-test cast iron is used for large Diesel engine crankshafts. Nickel alloy irons with tensile strengths of 60,000 to 75,000 psi have been used in casting large Diesel engine multicrankshafts weighing over a ton.

OVERHUNG CRANKS. Figures 1 and 2 show the proportions for cast-iron and forged-steel cranks. Although the sketches show different methods of securing the pin to the crankweb, the best practice is to use either a press or shrink fit, both for the pin and for attaching the crank to the shaft. A key is also used in the latter case. Let F = greatest load on the crankpin, when crank and connecting rod are at right angles; S = maximum allowable stress in the crank, pounds per square inch; L = distance from center of pin to section at which stress is to be computed, inches. Then dimensions may be checked for bending action at any section, as C–D (Fig. 2), by these equations:



Section XX

FIG. 1. Cast-iron side crank.

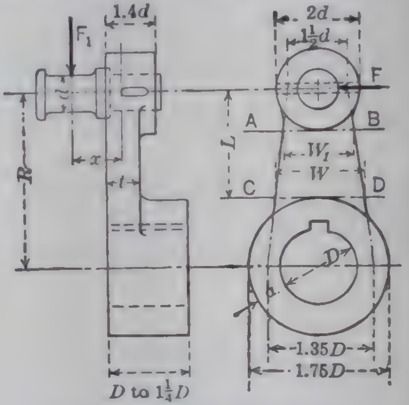


FIG. 2. Forged-steel side crank.

$$\text{Bending moment} = FL = tW^2\frac{S}{6} \tag{1}$$

$$t = \frac{6FL}{W^2S} \tag{2}$$

$$W = \sqrt{\frac{6FL}{tS}} \tag{3}$$

Let F_1 = greatest force acting on the crankpin when the crank is on dead centers. The bending moment at the section A–B (Fig. 2) then is

$$F_1x = \frac{W_1t^2S}{6} \tag{4}$$

$$W_1 = \frac{6F_1x}{t^2S} \tag{5}$$

$$t = \sqrt{\frac{6F_1x}{W_1S}} \tag{6}$$

S varies from 5000 psi for cast steel to 10,000 psi for the better steels. For cast-iron cranks t may be taken as $0.6D$. The diameter of the crankpin bosses d_1 may be taken as $d_1 = 1.16d + 0.02$ in. to $1.24d + 0.02$ in. The thickness of the bosses, v, may be taken as $0.75\ (d_1 - d)$.

The thickness of metal in the hub or boss of the crank (dimension a, Fig. 1), varies with the length of the boss. Values of a given by Seaton (D being the diameter of the crankshaft) are

M	$= 1.0D$	$0.9D$	$0.8D$	$0.7D$
a, iron	$= 0.35D$	$0.38D$	$0.40D$	$0.41D$
a, steel	$= 0.30D$	$0.32D$	$0.33D$	$0.34D$

FORGED CRANKSHAFTS. D. A. Low and A. W. Bevis (Ref. 1, p. 196) give the dimensions shown in Fig. 3, based on a large number of examples taken chiefly from marine practice. Sometimes a hole one-third the diameter of the pin is drilled through the crankpin as shown.

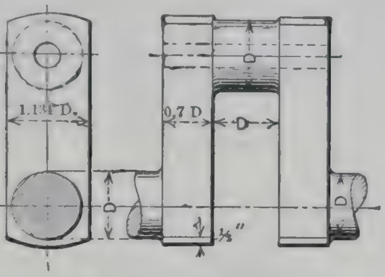

FIG. 3. Forged center crank.

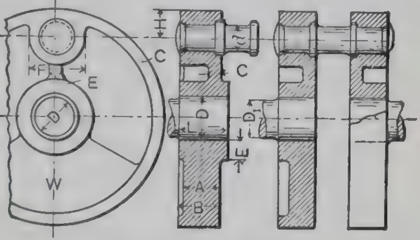

FIG. 4. Crankdisks.

CRANKDISKS (Fig. 4) are often used in small engines which run at high speed. The weight W, opposite the crankpin, is for the purpose of balancing the crankpin, and the part of the connecting rod which revolves with it. The following proportions may be used in designing crankdisks: $D_1 = D$ to $1.2D$; $B = 0.7D$ to D; $A = 0.9B$; $C = 0.25D$; $E = 0.4D$; $F = 2d$; $H = d$ to $1.5d$; $L = B$ to $1.25B$.

BALANCED CRANKS. Figure 5 shows a method of balancing cranks. When the size of the weight is determined by experiment the counterweight must be detachable as shown in Fig. 6. Figure 7 shows crankdisks where the center of mass of the balance weight does not fall opposite the crankpin.

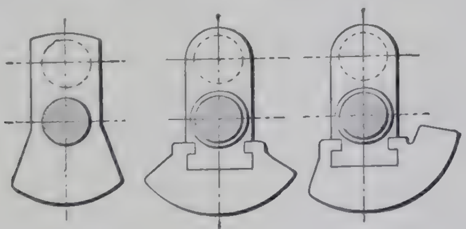

FIG. 5 FIG. 6 FIG. 7

Methods of balancing cranks.

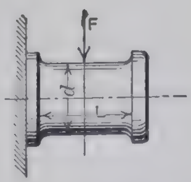

FIG. 8. Crankpin.

STRENGTH AND PROPORTIONS OF OVERHUNG CRANKPINS (Fig. 8). The dimensions of crankpins are based on the strength required to resist all the forces to which they will be subjected, and on the intensity of pressure permissible between pin and journal. This pressure must be kept low enough to avoid forcing lubricant out of the bearing, in which event heating and excessive wear would occur. Bending moment of the pin is $\frac{1}{2} FL$, where F = load on the pin, pounds, and L = length of pin, inches. If S = allowable maximum stress, pounds per square inch, and d = diameter of pin, inches, the resisting moment M_r, pound-inches, is $M_r = \pi d^3 S/32$. Hence

$$FL = \frac{d^3 S}{5.1} \tag{7}$$

and

$$d = 1.721 \sqrt[3]{\frac{FL}{S}} \tag{8}$$

The pin is subjected to reversed stresses and possible shock. The value of S will depend upon the material used. Values of 6000 to 10,000 psi may be used. For a given ratio of $L/d = B$, eq. 8 becomes

$$d = \sqrt{\frac{5.1BF}{S}} \tag{9}$$

To avoid heating, pins are usually made of larger dimensions than are given by eq. 9. Heating depends on the projected area of the bearing, dL. If P = bearing pressure, pounds per square inch, $F = PLd$ and $L = F/Pd$. Then eq. 8 becomes

$$d = \sqrt[4]{\frac{5.1F^2}{PS}} \tag{10}$$

The deflection of pins should not exceed 0.001 in.

STRENGTH OF CENTER-CRANK CRANKPINS. These may be treated as simple beams with the load concentrated at the center. In multiple-cylinder engines the torque from each cylinder is transmitted along the shaft and subjects the crankpins to torsional shear in addition to bending. The crank webs are assumed to have no effect upon the pins and the shaft is treated as if it were straight. See Shaft Design, Section 15, Article 2.

Table 1. Tangential Effort and Velocity Factors

Factor = $\sec \phi \sin (\theta + \phi)$

Forward stroke is toward crankshaft. Velocity of cross head = velocity of crankpin × tabular value.

Crank Angle, degrees, Forward Stroke	Ratio (Length of Connecting Rod/Length of Crank)											Crank Angle, degrees, Return Stroke

16. FORCES ACTING ON CRANKS

TANGENTIAL FORCES. In engines, if the center line of the crankshaft lies in the same plane as the center of the piston and the cross head, the effective force of the crank acts in a line tangent to the crank circle at any given position of the crank. This effective force is

$$F_t = P \sec \phi \sin (\theta + \phi) \tag{11}$$

where F_t = effective tangential force on the crankpin, pounds; P = total force acting on the piston, pounds = area of piston, square inches, × pressure on piston, pounds per square inch; θ = angle between crank and the line between center of crank and center of piston, angle CAB in Fig. 8, p. 7-03; ϕ = angle between connecting rod and the line between center of crank and center of piston, angle BCA in Fig. 8, p. 7-03. Table 1 gives values of $\sec \phi \sin (\theta + \phi)$ for various ratios of L/R, where L = length of connecting rod, inches, and R = radius of crank, inches. If the crank is used to impart motion to a cross head, as in a punch press, the resistance encountered by the cross head, i.e., the resistance of the metal to shearing or deformation, is taken as the value of P. The tangential force to be applied to the crank can then be computed, from which the horsepower required is determined.

Force acting along the center line of the connecting rod is

$$F_c = \frac{P}{\cos \phi} = \frac{P}{\sqrt{1 - \left(\frac{R \sin \theta}{L}\right)^2}} \tag{12}$$

The force acting on the guide is

$$F_g = P \tan \phi = \frac{P}{\sqrt{\left(\frac{L \csc \theta}{R}\right)^2 - 1}} \tag{13}$$

Note that P, pounds = (steam or gas pressure, pounds per square inch, + F_i from eq. 14) × A, square inches.

17. INERTIA FORCE OF PISTON

INERTIA FORCE OF PISTON in pounds per square inch of piston area is, approximately,

$$F_i = \frac{12WV_c^2}{gAR}\left(\cos \theta + \frac{R}{L} \cos 2\theta\right) \tag{14}$$

where all notation is as before and W = total weight of reciprocating parts, pounds; A = area of piston, square inches; g = acceleration due to gravity = 32.2 ft per sec per sec; and V_c = velocity of crankpin, feet per second. Table 2 gives values of $\cos \theta + (R/L) \cos 2\theta$ for various values of crank angles θ and ratios of L/R.

In eq. 14, F_i is actually $(W/gA) \times a$, where a is the acceleration of the piston, which may be obtained by double differentiation of eq. 2, p. 7-04. Equation 14 represents the first two terms of the Fourier series which may be used to express the acceleration. In balancing problems with multicylinder engines it is sometimes desired to know the values of additional harmonics, and eq. 14 may be written

$$F_i = \frac{12WV_c^2}{gAR}(\cos \theta + A_2 \cos 2\theta - A_4 \cos 4\theta + A_6 \cos 6\theta) \tag{14a}$$

where

$$A_2 = \frac{R}{L} + \frac{R^3}{4L^3} + \frac{15R^5}{128L^5}$$

$$A_4 = \frac{R^3}{16L^3} + \frac{R^5}{64L^5}$$

$$A_6 = \frac{R^5}{128L^5}$$

Table 2. Inertia and Acceleration Factors

Values of $\cos\theta + (R/L)\cos 2\theta$

Acceleration of crosshead = normal acceleration of crankpin × tabular value

18. CONNECTING RODS

Types of connecting rods for large engines are shown in Figs. 9 to 13. The solid rod shown in Fig. 9 is the strongest and most common form used with side-crank engines. Connecting rods for center-crank engines are made with the crankpin end in two or more pieces to facilitate assembly on the crankpin. Wedge blocks placed as shown in Fig. 11 have maximum accessibility for adjustment; wear should be taken up in the same direction on both bearings to maintain the original rod length. Wedges should always be placed so that the bolts pull the wedges down when tightened, reducing the danger of excessive end play and of piston striking cylinder head if the bolt should break. The crankpin end is generally provided with a babbitt-lined bearing box. Bronze bearings give better service

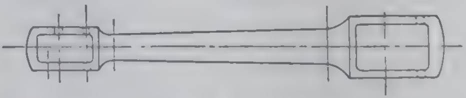

FIG. 9. Solid connecting rod.

at the wrist pin, where the pressures are high and the space limited. Rods for single-acting engines using trunk pistons are usually not made adjustable because of the inaccessibility.

DESIGN. The body of the rod is designed as a column with pin ends subjected to an additional bending load due to the inertia of the oscillating rod. The stress due to the column action is

$$s = \frac{F_c}{A\left[1 - \frac{s_y}{4n\pi^2 E}\left(\frac{L}{k}\right)^2\right]} \tag{15}$$

where F_c is obtained from eq. 12; A = cross-sectional area, square inches; s_y = yield stress of the material, pounds per square inch; n = column-end factor (unity for pin ends); E = modulus of elasticity; L = length center to center of pins, inches; k = radius of gyration of the cross section, inches. The rod may be assumed to be uniform in cross section, without any appreciable error, in which case the resultant inertia force due to the acceleration of the oscillating rod will act at a distance $2L/3$ from the wrist pin and will have a magnitude

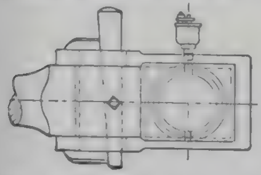

FIG. 10. Open-strap and key design of connecting-rod end for low-speed engines.

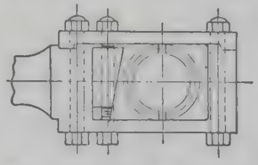

FIG. 11. Open-side and strap design of connecting-rod end.

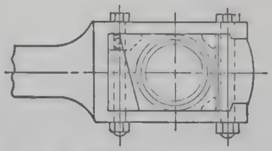

FIG. 12. Open-end and block design of connecting-rod end.

$$F_1 = \frac{12Wv^2}{2gR}\sin\theta \tag{16}$$

where W = the weight of the body of the rod, pounds; v = the velocity of the crankpin, feet per second; R = the radius of the crank, inches; and θ = crank angle. The maximum bending moment, M, pound-inches, caused by this force will be at a distance $0.577L$ from the wrist pin, and its value will be

$$M = 0.774\frac{Wv^2}{g}\frac{L}{R}\sin\theta \tag{17}$$

The permissible stress should not exceed one-third the yield stress for single-acting engines, or one-sixth the yield stress for double-acting engines, since the stresses are repeated or reversed. The rod may be round, rectangular, or I-sectioned. The ratio of width to depth of a rectangular section should be 0.5 to 0.7.

Rods with I-sections must be proportioned for stiffness to prevent local buckling even when the column and bending equations indicate sufficient strength. I-section rods have a width 0.6 times the depth and a flange and web thickness 0.20 to 0.25 times the depth. Most rods are tapered so that the crankpin end is 1.10 to 1.15 times the depth computed for the center section. The outer end of solid rods and the cap of marine-type and split-end rods may be assumed to be simple beams supported at the center. The deflection computed for this beam should not exceed 0.001 in.

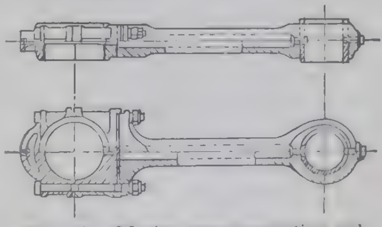

FIG. 13. Marine-type connecting rod.

19. FLYWHEELS

A flywheel is primarily a rotating energy reservoir performing two distinct classes of service. First, the flywheel absorbs energy from a power source during the greater portion of the operating cycle and delivers a large amount of energy as useful work in a very short portion of the cycle. This class includes punch presses and shears. In the second class, including steam engines, internal-combustion engines, compressors, and reciprocating pumps, the flywheel smooths out the speed fluctuations caused by nonuniform flow of power from the pistons during each energy cycle.

FLYWHEEL ACTION. The kinetic energy E, foot-pounds, in the rim of a rotating flywheel is

$$E = \frac{Wv^2}{2g} \tag{18}$$

where W = weight of rim, pounds; v = mean velocity of rim, feet per second; and g = acceleration due to gravity = 32.2 ft per sec per sec. If the velocity changes from v_1 to v_2 the energy fluctuation is

$$\Delta E = \frac{W(v_1^2 - v_2^2)}{2g} \tag{19}$$

From eq. 19,

$$W = \frac{2g\Delta E}{v_1^2 - v_2^2} \tag{20}$$

$$\Delta E = \frac{W(v_1 + v_2)(v_1 - v_2)}{2g} = \frac{aWv^2}{2g} \tag{21}$$

where $a = (v_1 - v_2)/v$ and is called the *coefficient of fluctuation.*

Coefficient of Fluctuation. The *coefficient of steadiness* b = the reciprocal of the coefficient of fluctuation $= v/(v_1 - v_2)$. From eq. 21,

$$W = \frac{2g\Delta E}{av^2} = \frac{2g\Delta Eb}{v^2} \tag{22}$$

Since the linear velocity is $v = 2\pi kn/60$, where k = radius of gyration of rim, feet, and n = angular velocity of wheel, revolutions per minute:

$$\Delta E = \frac{Wk^2n^2}{91.2bg} = \frac{In^2}{91.2bg} \tag{23}$$

where the mass moment of inertia about the axis of rotation is $I = Wk^2/g$, sometimes called the *flywheel effect*. In this case the coefficient of steadiness is $b = n/(n_1 - n_2)$.

From eq. 23,

$$W = \frac{91.2bg\Delta E}{n^2k^2} \tag{24}$$

Table 3. Values of Coefficient of Steadiness, *b*, for Flywheels

Engines Operating	*b*	Authority
Crushing machinery	5	Mayer
Electrical machinery	300	Unwin
Electrical machinery direct driven	150	Unwin
Engines with belt transmission	35	Mayer
Flour milling machinery	50	Mayer
Gear-wheel transmission	50	Mayer
Hammering machinery	5	Mayer
Machine tools	35	Unwin
Paper-making machinery	40	Mayer
Pumping machinery	20– 30	Mayer
Shearing machinery	20– 30	Mayer
Spinning machinery	50–100	Mayer; Unwin
Textile machinery	40	Unwin

Values of the coefficient of steadiness are given in Table 3. Since the moment of inertia of the hub and arms is seldom over 5 to 10%, it is customary to neglect the weight of the hub and arms and assume the total weight of flywheel to be in the rim. The energy to be absorbed by a flywheel may be found either analytically or graphically. The latter method is the more convenient when the work input is variable, and data are available to draw an energy diagram.

STRESSES IN FLYWHEELS are rather complicated because of the effect of centrifugal force in the rim and arms and unknown shrinkage stresses caused by unequal cooling rates of the metal in the rim, arms, and hub. The rim is subjected to centrifugal force whose magnitude at the mean circumference is

$$F_c = \frac{12wbv^2}{gr} \tag{25}$$

where w = weight of material, pounds per cubic inch; b = rim thickness, inches; v = mean velocity, feet per second; r = mean radius, inches; and g = 32.2. This force F_c acting on a rotating rim without restraining arms produces hoop stress in pounds per square inch:

$$S_c = \frac{12wv^2}{g} \tag{26}$$

The section of the rim between the arms may be considered as a fixed-end beam with the centrifugal force uniformly distributed. The bending stress is

$$S_b = \frac{12\pi^2 Dwv^2}{gbn^2} \tag{27}$$

where D = mean diameter, inches, and n = number of arms.

Since the arms are not rigid, the actual stress in the rim at the junction with an arm is approximately

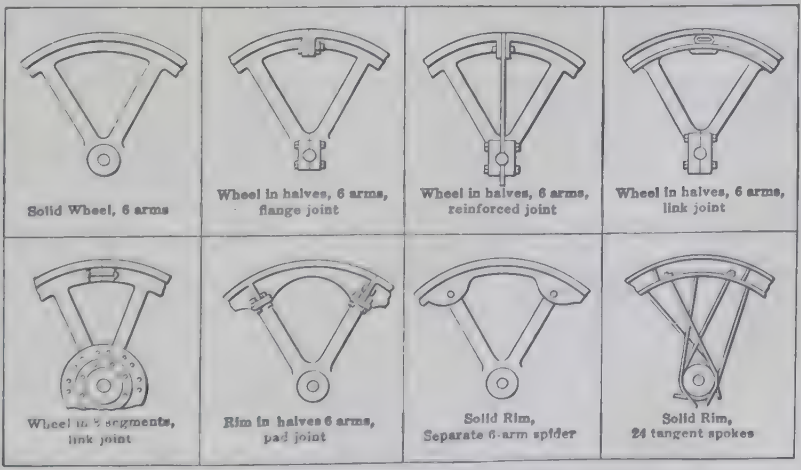
$$S = \frac{3S_e}{4} + \frac{S_b}{4} = \frac{wv^2}{g}\left(9 + \frac{3\pi^2 D}{bn^2}\right) \tag{28}$$

For cast iron $S = 6000$ psi and $w = 0.26$ lb per cu in. For cast steel $S = 24{,}000$ psi and $w = 0.28$ lb per cu in. For cast iron, rim velocities should be limited to 6000 ft per min when the rim, arms, and hubs are cast in one piece. For cast steel the velocity is limited to 8000 ft per min. In order to eliminate shrinkage stresses, the flywheel may be cast in sections and bolted together, or the rim may be cast one day with a number of wrought-steel spokes inserted in the mold and the hub cast on these the following day. Velocities up to 12,000 ft per min may be attained with the type. Flywheels with rims and hubs cast separately and bolted together by steel disks or webs may run at velocities up to 15,000 ft per min. The ratio of the width to height of rim section varies from 0.6 to 2. If a belt is run on flywheel the face must be at least 1 in. wider than the belt. The arms are designed to carry the full torque of the machine. Each arm is assumed to act as a cantilever beam fixed at the hub and carrying its proportionate share of the load concentrated at the free end at the rim. The moment $M = T(D - d)/D$, inch-pounds, and the stress is

$$S = \frac{T(D - d)}{N_a ZD} \tag{29}$$

where N_a = number of arms and Z = section modulus of the arm cross section at the hub. S for cast iron should not exceed 2000 psi and, if there is severe shock, as in pumps, not over 1000 psi. For an elliptical section $Z = \pi b^2h/32$, where h = thickness and b = width of section. The arms should taper both in breadth and depth from the hub to the rim an amount of 1/4 in. per ft. The usual number of arms is six, but these may be eight, ten, or twelve, depending upon rim width and diameter of flywheel. For an elliptical section $b/h = 2$. The hub diameter = twice shaft diameter and hub length = 2 to 2.5 times shaft diameter.

FLYWHEEL CONSTRUCTION. Various types of flywheel construction are shown in Fig. 14. The solid rim wheel, usually made up to 8 ft in diameter, is the strongest. The wheel made in halves with a flange joint between arms is the weakest. Flywheels made in two sections should be joined on an arm. Results of tests by Professor C. H. Benjamin



Solid Wheel, 6 arms

Wheel in halves, 6 arms, flange joint

Wheel in halves, 6 arms, reinforced joint

Wheel in halves, 6 arms, link joint

Wheel in 8 segments, link joint

Rim in halves 6 arms, pad joint

Solid Rim, Separate 6-arm spider

Solid Rim, 24 tangent spokes

FIG. 14. Types of flywheel joints.

(Ref. 2) on the destruction of various types of flywheels shown in Fig. 14 are given in Table 4.

Table 4. Results of Tests to Destruction of Various Types of Flywheels

Type of wheel (see Fig. 14)	1	2	3	4	5	6	7	8
Rim speed at failure, ft per sec	395	194	225	305	256	223	393	424
Rim speed at failure, ft per min	23 700	11,640	13.500	18,300	15,360	13,380	23,580	25.440
Apparent rim stress at failure, psi	15 625	3 764	5.062	9,302	6,502	4,973	15,445	17,978
Comparative rim speeds at failure	100	49	57	77	65	56.5	100	107
Comparative rim stress at failure	100	24	32.5	60	42	32	99	115

The Haight construction is shown in Fig. 15. The rim section carrying the section necessary for the links joining the parts of the wheel is cut away around the entire circumference of the rim. The rim proper, therefore, is continuous and is not weakened by the drilling of holes or otherwise cutting it away for the reception of fastening members. The net result is to give a rim of I-section which is better fitted to resist stresses than the ordinary shape of rim. Furthermore, by having the joints come at the ends of the arms, which are made double at the joints, as shown in Fig. 15, the rim is continuous between arms and the tendency to failure at the joint is minimized.

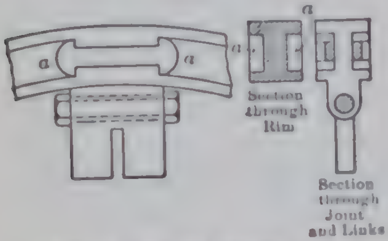


Fig. 15. Haight flywheel joint.

Various designs of flywheel have been made for different purposes. In one type of engine flywheel, the rim section is cast integral with the arms. The rim section is divided into two parts on a plane perpendicular to the axis of the wheel, each part having its own set of arms. The hub is cast separately, and the two halves of the rim section and the hub are fastened together by through bolts through the rim and the hub. Another type, for a rim speed of 15,000 ft per min, has been built with a rim formed of laminated plates. A cast-steel spider with twelve double arms had dovetail notches cut in its periphery. The laminated plates, cut in arcs of 30 degrees, were machined on the inside circumference to fit the notches on the spider, and assembled with broken joints. Side cover plates, machined with a groove into which the edge of the spider rim fits, were then placed outside the laminated plates, and the entire assembly bolted together with ten turned-and-fitted through bolts in each pair of side plates. The wheel was 13 ft outside diameter, 2 ft 2 in. face, and weighed about 100,000 lb.

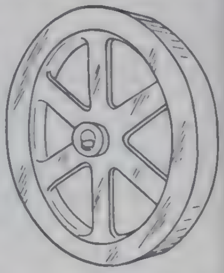

Fig. 16. Cast-iron flywheel for punch press.

Bandsaw flywheels usually run at rim velocities of 10,000 ft per min and may at times run even higher. The Allis-Chalmers Company uses a construction in which the rim is of V-section and the arms are arranged diagonally, passing from one side of the hub to the opposite side of the rim, alternate arms being staggered with respect to each other. Another construction, largely used in bandsaw wheels, uses spokes composed of steel bars, either round, or square and set diagonal to the plane of rotation of the wheel, which are cast into the wheel and hub. Two rows of spokes are used, alternate spokes extending from the central plane of the rim to the opposite sides of the hub. The rim is poured first, and after it has cooled the hub is poured. Shrinkage strains in the rim that might pull the hub out of line thus are avoided. Construction of flywheels by welding steel plate not only eliminates blow holes often appearing in cast construction but also reduces cost of construction. Figure 16 shows a flywheel of cast construction. Figure 17 shows a flywheel for the same purpose, of welded steel.

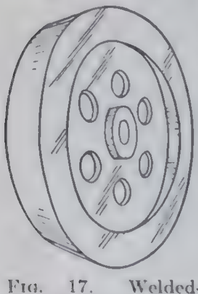

Fig. 17. Welded-steel flywheel to replace that shown in Fig. 16. (Courtesy of Lincoln Electric Co., Cleveland, Ohio)

For descriptions and illustrations of the construction details of a great variety of flywheels, including the above, for many different services, see Ref. 3.

ROTATING DISKS. Flywheels in the form of a disk, or those in which the depth of the rim is so great as compared to the rim that they approximate a disk form, cannot be designed by the methods used for the conventional type of flywheel. The complete determination of the stresses requires an involved mathematical analysis, which is complicated by the lack of experimental data. Kimball and Barr (Ref. 4) give the following equations for the radial and tangential stresses in a rapidly rotating plain disk: Let R, r = respectively, outer and inner radii of disk, inches; r_1 = radius at any point, inches; S_t, S_r = respectively, tangential and radial stresses at any radius r_1; w = weight of material, pounds per cubic inch; n = revolutions per minute; λ = Poisson's ratio = 0.3 for steel = 0.25 for cast iron. C = a constant = 0.00000355. Then for a solid disk,

$$S_t = Cwn^2[(3 + \lambda)R^2 - (1 + 3\lambda)r_1^2] \tag{30}$$

$$S_r = Cwn^2[(3 + \lambda)(R^2 - r_1^2)] \tag{31}$$

For a disk with a hole at the center,

$$S_t = Cwn^2\left[(3 + \lambda)\left(R^2 + r^2 + \frac{R^2r^2}{r_1^2}\right) - (1 + 3\lambda)r_1^2\right] \tag{32}$$

$$S_r = Cwn^2\left[(3 + \lambda)\left(R^2 + r^2 - \frac{R^2r^2}{r_1^2} - r_1^2\right)\right] \tag{33}$$

By taking r so small that r^2 is a negligible value, it can be shown that the tangential stress at the surface of the bore is twice that obtained by putting $r = 0$ in eq. 30. This shows that even a small hole at the center of a rotating disk will greatly increase the tangential stress in the disk.

Rotating disks in which the stresses are to be uniform at all points, as steam turbine disks, will be of varying cross section and thicker at the hub than at the periphery. The design of such disks involves complicated mathematical analysis. For one method of analysis, as used for steam turbine disks, see Kent's *Mechanical Engineers' Handbook —Power*, Section 8.

STATIC STRESSES

1. FUNDAMENTAL DEFINITIONS

TOTAL STRESS on a section mn through a loaded body is the resultant force S exerted by one part of the body on the other part in order to maintain in equilibrium the external loads acting on the part. Thus, in Figs. 1, 2, and 3, the total stress on section mn due to the external load P is S. The units in which it is expressed are those of load, i.e., pounds, tons, etc.

UNIT STRESS more commonly called stress σ, is the total stress per unit of area at section mn. In general it varies from point to point over the section. Its value at any point of a section is the total stress on an elementary part of the area, including the point divided by the elementary area. If in Figs. 1, 2, and 3 the loaded bodies are one unit thick and four units wide, then when the total stress S is uniformly distributed over the area, $\sigma = P/A = P/4$. Unit stresses are expressed in pounds per square inch, tons per square foot, etc.

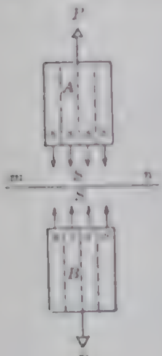

FIG. 1

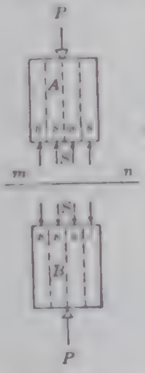

FIG. 2

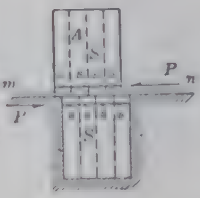

FIG. 3

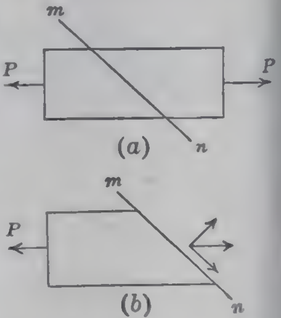
FIG. 1. Tensile stress. FIG. 2. Compressive stress. FIG. 3. Shear stress.

TENSILE STRESS OR TENSION is the internal total stress S exerted by the material fibers to resist the action of an external force P (Fig. 1), tending to separate the material into two parts along the line mn. For equilibrium conditions to exist, the tensile stress at any cross section will be equal and opposite in direction to the external force P. If the internal total stress S is distributed uniformly over the area, the stress can be considered as unit tensile stress $\sigma = S/A$.

COMPRESSIVE STRESS OR COMPRESSION is the internal total stress S exerted by the fibers to resist the action of an external force P (Fig. 2) tending to decrease the length of the material. For equilibrium conditions to exist, the compressive stress at any cross section will be equal and opposite in direction to the external force P. If the internal total stress S is distributed uniformly over the area, the unit compressive stress $\sigma = S/A$.

SHEAR STRESS is the internal total stress S exerted by the material fibers along the plane mn (Fig. 3) to resist the action of the external forces, tending to slide the adjacent parts in opposite directions. For equilibrium conditions to exist, the shear stress at any cross section will be equal and opposite in direction to the external force P. If the internal total stress S is uniformly distributed over the area, the unit shear stress $\tau = S/A$.

NORMAL STRESS is the component of the resultant stress which acts normal to the area considered (Fig. 4).



(a)

(b)

FIG. 4. Normal and shear stress components of resultant stress on section mn.

AXIAL STRESS is a special case of normal stress and may be either tensile or compressive. It is the stress existing in a straight homogeneous bar when the resultant of the applied loads coincides with the axis of the bar.

SIMPLE STRESS exists when either tension, compression, or shear is considered to operate singly on a body.

TOTAL STRAIN on a loaded body is the total elongation produced by the influence of an external load. Thus, in Fig. 5, the total strain is equal to δ. It is expressed in units of length, i.e., inches, feet, etc.

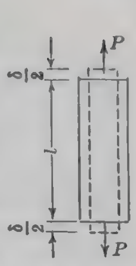


FIG. 5. Strain due to tension.

UNIT STRAIN or deformation per unit length is the total amount of deformation divided by the original length of the body before the load causing the strain was applied. Thus, if the total elongation is δ in an original gage length l, the unit strain $e = \delta/l$. Unit strains are expressed in inches per inch and feet per foot.

TENSILE STRAIN is the strain produced in a specimen by tensile stresses, which in turn are caused by external forces.

COMPRESSIVE STRAIN is the strain produced in a bar by compressive stresses, which in turn are caused by external forces.

SHEAR STRAIN is a strain produced in a bar by the external shearing forces.

POISSON'S RATIO is the ratio of lateral unit strain to longitudinal unit strain under the conditions of uniform and uniaxial longitudinal stress within the proportional limit. It serves as a measure of lateral stiffness. Average values of Poisson's ratio for the usual materials of construction are:

Material	Steel	Wrought Iron	Cast Iron	Brass	Concrete
Poisson's ratio	0.300	0.280	0.270	0.340	0.100

ELASTICITY is that property of a material which enables it to deform or undergo strain and return to its original shape upon the removal of the load.

HOOKE'S LAW states that within certain limits (not to exceed the proportional limit) the elongation of a bar produced by an external force is proportional to the tensile stress developed. Hooke's law gives the simplest relation between stress and strain.

PLASTICITY is that state of matter where permanent deformations or strains may occur without fracture. A material is plastic if the smallest load increment produces a permanent deformation. A perfectly plastic material is nonelastic and has no ultimate strength in the ordinary meaning of that term. Lead is a plastic material. A prism tested in compression will deform permanently under a small load and will continue to deform as the load is increased, until it flattens to a thin sheet. Wrought iron and steel are plastic when stressed beyond the elastic limit in compression. When stressed beyond the elastic limit in tension, they are partly elastic and partly plastic, the degree of plasticity increasing as the ultimate strength is approached.

STRESS-STRAIN RELATIONSHIP gives the relation between unit stress and unit strain when plotted on a stress-strain diagram in which the ordinate represents unit stress and the abscissa unit strain. Figure 6 shows a typical tension stress-strain curve for medium steel. The form of the curve obtained will vary according to the material, and the curve for compression will be different from the one for tension. For some materials like cast iron, concrete, and timber, no part of the curve is a straight line.

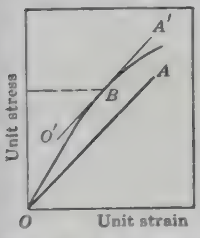

FIG. 6. Stress-strain relationship showing determination of apparent elastic limit.

PROPORTIONAL LIMIT is that unit stress at which unit strain begins to increase at a faster rate than unit stress. It can also be thought of as the greatest stress which a material can stand without deviating from Hooke's law. It is determined by noting on a stress-strain diagram the unit stress at which the curve departs from a straight line.

ELASTIC LIMIT is the least stress that will cause permanent strain, i.e., the maximum unit stress to which a material may be subjected and still be able to return to its original form upon removal of the stress.

Johnson's Apparent Elastic Limit. In view of the difficulty of determining precisely for some materials the proportional limit, J. B. Johnson proposed as the "apparent elastic limit" the point on the stress-strain diagram at which the rate of strain is 50% greater than at the original. It is determined by drawing *OA* (Fig. 6) with a slope with respect to the vertical axis 50% greater than the straight-line part of the curve; the unit stress at which the line *O′A′* which is parallel to *OA* is tangent to the curve (point *B*, Fig. 6) is the apparent elastic limit.

YIELD POINT is the lowest stress at which strain increases without increase in stress. Only a few materials exhibit a true yield point. For other materials the term is sometimes used as synonymous with yield strength.

YIELD STRENGTH is the unit stress at which a material exhibits a specified permanent deformation or state. It is a measure of the useful limit of materials, particularly of those whose stress-strain curve in the region of yield is smooth and of gradual curvature.

ULTIMATE STRENGTH is the highest unit stress a material can sustain in tension, compression, or shear before rupturing.

RUPTURE STRENGTH OR BREAKING STRENGTH is the unit stress at which a material breaks or ruptures. It is observed in tests on steel to be slightly less than the ultimate strength because of a large reduction in area before rupture.

MODULUS OF ELASTICITY (Young's modulus) in tension and compression is the rate of change of unit stress with respect to unit strain for the condition of uniaxial stress within the proportional limit. For most materials the modulus of elasticity is the same for tension and compression.

MODULUS OF RIGIDITY (modulus of elasticity in shear) is the rate of change of unit shear stress with respect to unit shear strain for the condition of pure shear within the proportional limit. For metals it is equal to approximately 0.4 of the modulus of elasticity.

TRUE STRESS is defined as a ratio of applied axial load to the corresponding cross-sectional area. The units of true stress may be expressed in pounds per square inch, pounds per square foot, etc.

$$\sigma = \frac{P}{A}$$

where σ is the true stress, pounds per square inch, P is the axial load, pounds, and A is the smallest value of cross-sectional area existing under the applied load P, square inches.

TRUE STRAIN is defined as a function of the original diameter to the instantaneous diameter of the test specimen:

$$q = 2 \log_e \frac{d_0}{d} \text{ in./in.}$$

where q = true strain, inches per inch, d_0 = original diameter of test specimen, inches, and d = instantaneous diameter of test specimen, inches.

TRUE STRESS-STRAIN RELATIONSHIP is obtained when the values of true stress and the corresponding true strain are plotted against each other in the resulting curve (Fig. 7). The slope of the nearly straight line leading up to fracture is known as the coefficient of strain hardening. It as well as the true tensile strength appear to be related to the other mechanical properties.

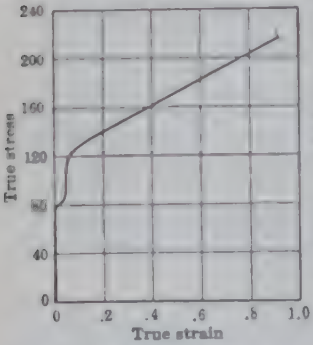

FIG. 7. True stress-strain relationship.

DUCTILITY is the ability of a material to sustain large permanent deformations in tension, as drawing into a wire.

MALLEABILITY is the ability of a material to sustain large permanent deformations in compression, as beating or rolling into thin sheets.

BRITTLENESS is that property of a material that permits it to be only slightly deformed without rupture. Brittleness is relative, no material being perfectly brittle, that is, capable of no deformation before rupture. Many materials are brittle to a greater or less degree, glass being one of the most brittle of materials. Brittle materials have relatively short stress-strain curves. Of the common structural materials, cast iron, brick, and stone are brittle in comparison with steel.

TOUGHNESS is the ability of the material to withstand high unit stress together with great unit strain, without complete fracture. The area *OAGH*, or *OJK*, under the curve of the stress-strain diagram (Fig. 8), is a measure of the toughness of the material. The distinction between ductility and toughness is that ductility deals only with the ability to deform, whereas toughness considers both the ability to deform and the stress developed during deformation.

STIFFNESS is the ability to resist deformation under stress. The modulus of elasticity is the criterion of the stiffness of a material.

HARDNESS is the ability to resist very small indentations, abrasion, and plastic deformation. There is no single measure of hardness, as it is not a single property but a combination of several properties.

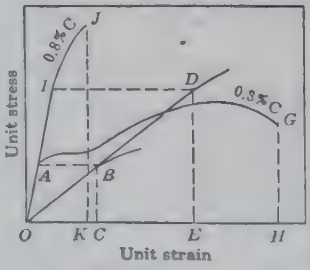

FIG. 8. Toughness comparison.

CREEP or flow of metals is a phase of plastic or inelastic action. Some solids, as asphalt or paraffin, flow appreciably at room temperatures under extremely small stresses; zinc, lead, and tin show signs of creep at room temperature under moderate stresses. At sufficiently high temperatures, practically all metals creep under stresses which vary with temperature, the higher the temperature the lower being the stress at which creep takes place. The deformation due to creep continues to increase indefinitely and becomes of extreme importance in members subjected to high temperatures, as parts in turbines, boilers, super-heaters, etc.

Creep limit is the maximum unit stress under which unit distortion will not exceed a specified value during a given period of time at a specified temperature. A value much used in tests, and suggested as a standard for comparing materials, is the maximum unit stress at which creep does not exceed 1% in 100,000 hours.

TYPES OF FRACTURE. A bar of brittle material, as cast iron, will rupture in a tension test in a clean sharp fracture with very little reduction of cross-sectional area and very little elongation (Fig. 9*a*). In a ductile material, as structural steel, the reduction of area and elongation are greater (Fig. 9*b*). In compression, a prism of brittle material will break by shearing along oblique planes; the greater the brittleness of the material, the more nearly will these planes parallel the direction of the applied force. Figures 10*a*, 10*b*, and 10*c*, arranged in order of brittleness, illustrate the type of fracture in prisms of brick, concrete, and timber. Figure 10*d* represents the deformation of a prism of plastic material, as lead, which flattens out under load without failure.

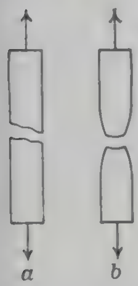

FIG. 9. Brittle (*a*) and ductile (*b*) fractures in tension.

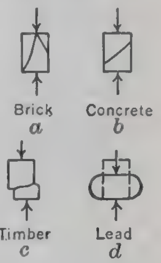

FIG. 10. Fractures in compression.

RELATIONS OF ELASTIC CONSTANTS

Modulus of elasticity, E

$$E = \frac{Pl}{Ae}$$

where P = load, pounds, l = length of bar, inches, A = cross-sectional area acted on by the axial load P, and e = total strain produced by axial load P.

Modulus of rigidity, G

$$G = \frac{E}{2(1+\nu)}$$

where E = modulus of elasticity and ν = Poisson's ratio.

Bulk modulus, K, is the ratio of normal stress to the change in volume.

Relationships. The following relationships exist between the modulus of elasticity, E, the modulus of rigidity G, the bulk modulus of elasticity K, and Poisson's ratio, ν:

$$E = 2G(1+\nu); \qquad G = \frac{E}{2(1+\nu)}; \qquad \nu = \frac{E-2G}{2G}$$

$$K = \frac{E}{3(1-2\nu)}; \qquad \nu = \frac{3K-E}{6K}$$

ALLOWABLE UNIT STRESS, also called allowable working unit stress, allowable stress, or working stress, is the maximum unit stress to which it is considered safe to subject a member in service. The term allowable stress is preferable to working stress, since the latter often is used to indicate the actual stress in a material when in service. Allowable unit stresses for different materials for various conditions of service are specified by different authorities on the basis of test or experience. In general, for ductile materials, allowable stress is considerably less than the yield point.

FACTOR OF SAFETY is the ratio of ultimate strength of the material to allowable stress. The term was originated for determining allowable stress. The ultimate strength of a given material divided by an arbitrary factor of safety, dependent on material and the use to which it is to be put, gives the allowable stress. In present design practice, it is customary to use allowable stress as specified by recognized authorities or building codes rather than an arbitrary factor of safety. One reason for this is that the factor of safety is misleading, in that it implies a greater degree of safety than actually exists. For example, a factor of safety of 4 does not mean that a member can carry a load four times as great as that for which it was designed. It also should be clearly understood that, even though each part of a machine is designed with the same factor of safety, the machine as a whole does not have that factor of safety. When one part is stressed beyond the proportional limit, or particularly the yield point, the load or stress distribution may be completely changed throughout the entire machine or structure, and its ability to function thus may be changed, even though no part has ruptured.

Although no definite rules can be given, if a factor of safety is to be used, the following circumstances should be taken into account in its selection.

(a) When the ultimate strength of the material is known within narrow limits, as for structural steel for which tests of samples have been made, when the load is entirely a steady one of a known amount and there is no reason to fear the deterioration of the metal by corrosion, the lowest factor that should be adopted is 3.

(b) When the circumstances of (a) are modified by a portion of the load being variable, as in floors of warehouses, the factor should not be less than 4.

(c) When the whole load, or nearly the whole, is likely to be alternately put on and taken off, as in suspension rods of floors of bridges, the factor should be 5 or 6.

(d) When the stresses are reversed in direction from tension to compression, as in some bridge diagonals and parts of machines, the factor should be not less than 6.

(e) When the piece is subjected to repeated shocks the factor should be not less than 10.

(f) When the piece is subjected to deterioration from corrosion the section should be sufficiently increased to allow for a definite amount of corrosion before the piece is so far weakened by it as to require removal.

(g) When the strength of the material or the amount of the load or both are uncertain the factor should be increased by an allowance sufficient to cover the amount of the uncertainty.

(h) When the strains are complex and of uncertain amount, such as those in the crankshaft of a reversing engine, a very high factor is necessary, possibly even as high as 40.

(i) If the property loss caused by failure of the part may be large or if loss of life may result, as in a derrick hoisting materials over a crowded street, the factor should be large.

2. BEAMS—THEORY OF FLEXURE

TYPES OF BEAMS. A beam is a bar or structural member subjected to transverse loads that tend to bend it. Any structural member acts as a beam if bending is induced by external transverse forces.

A simple beam (Fig. 11*a*) is a horizontal member that rests on two supports at the ends of the beam. All parts between the supports have free movement in a vertical plane under the influence of vertical loads.

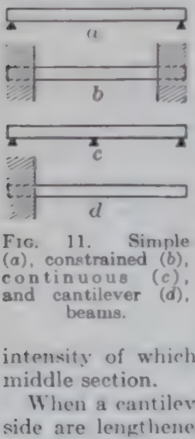

Fig. 11. Simple (*a*), constrained (*b*), continuous (*c*), and cantilever (*d*), beams.

A fixed beam, constrained beam, or restrained beam (Fig. 11*b*) is rigidly fixed at both ends or rigidly fixed at one end and simply supported at the other.

A continuous beam (Fig. 11*c*) is a member resting on more than two supports.

A cantilever beam (Fig. 11*d*) is a member with one end projecting beyond the point of support, free to move in a vertical plane under the influence of vertical loads placed between the free end and the support.

PHENOMENA OF FLEXURE. When a simple beam bends under its own weight the fibers on the upper or concave side are shortened, and the stress acting on them is compression; the fibers on the under or convex side are lengthened, and the stress acting on them is tension. In addition, shear exists along each cross section, the intensity of which is greatest along the sections at the two supports and zero at the middle section.

When a cantilever beam bends under its own weight the fibers on the upper or convex side are lengthened under tensile stresses; the fibers on the under or concave side are shortened under compressive stresses; the shear is greatest along the section at the support, and zero at the free end.

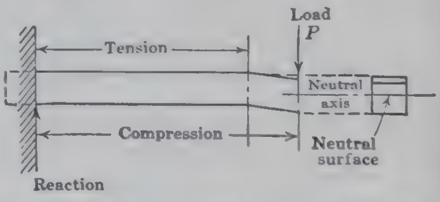

Fig. 12. Loads and stress conditions in a cantilever beam.

THE NEUTRAL SURFACE is that horizontal section between the concave and convex surfaces of a loaded beam, where there is no change in the length of the fibers and no tensile or compressive stresses acting upon them.

THE NEUTRAL AXIS is the trace of the neutral surface on any cross section of a beam. (See Fig. 12.)

THE ELASTIC CURVE of a beam is the curve formed by the intersection of the neutral surface with the side of the beam, it being assumed that the longitudinal stresses on the fibers are within the elastic limit.

REACTIONS AT SUPPORTS. The reactions, or upward pressures at the points of support, are computed by applying the following conditions necessary for equilibrium of a system of vertical forces in the same plane: (1) The algebraic sum of all vertical forces must equal zero; i.e., the sum of the reactions equals the sum of the downward loads.

(2) The algebraic sum of the moments of all the vertical forces must equal zero. Condition (1) applies to cantilever beams and to simple beams uniformly loaded, or with equal concentrated loads placed at equal distances from the center of the beam. In the cantilever beam, the reaction is the sum of all the vertical forces acting downward, comprising the weight of the beam and the superposed loads. In the simple beam each reaction is equal to one-half the total load, consisting of the weight of the beam and the superposed loads. Condition (2) applies to a simple beam not uniformly loaded. The reactions are computed separately, by determining the moment of the several loads about each support. The sum of the moments of the load around one support is equal to the moment of the reaction of the other support around the first support.

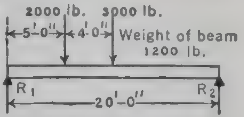

Fig. 13. Example of a simple loaded beam.

Example. Determine reactions R_1, R_2 of a simple beam 20 ft long, loaded as in Fig. 13. The weight of the beam may be taken as a concentrated load applied at the center of gravity of the beam. Then, moments around left-hand and right-hand supports are, respectively,

$$\text{Left-hand:}\quad (2000 \times 5) + (3000 \times 9) + (1200 \times 10) - (R_2 \times 20) = 0; \qquad R_2 = 2450 \text{ lb}$$
$$\text{Right-hand:}\quad (R_1 \times 20) - (2000 \times 15) - (3000 \times 11) - (1200 \times 10) = 0; \qquad R_1 = 3750 \text{ lb}$$
$$R_1 + R_2 = 6200 \text{ lb} = \text{sum of all loads acting downward}$$

CONDITIONS OF EQUILIBRIUM. The fundamental laws for the stresses at any cross section of a beam in equilibrium are: (1) Sum of horizontal tensile stresses = sum of horizontal compressive stresses. (2) Resisting shear = vertical shear. (3) Resisting moment = bending moment.

Vertical Shear. At any cross section of a beam the resultant of the external vertical forces acting on one side of the section is equal and opposite to the resultant of the external vertical forces on the other side of the section. These forces tend to cause the beam to shear vertically along the section. The value of either resultant is known as the vertical shear at the section considered. It is computed by finding the algebraic sum of the vertical forces to the left of the section; that is, it is equal to the left reaction minus the sum of the vertical downward forces acting between the left support and the section.

A shear diagram is a graphic representation of the vertical shear at all cross sections of the beam. Thus in the simple beam (Fig. 14) the ordinates to the line *AOB* represent to scale the intensity of the vertical shear at the corresponding sections of the beam. The vertical shear is greatest at the supports, where it is equal to the reactions, and it is zero at the center of the span. In the cantilever beam (Fig. 15) the vertical shear is greatest at the point of support, where it is equal to the reaction, and it is zero at the free end. Figure 16 shows graphically the vertical shear on all sections of a simple beam carrying two concentrated loads at equal distances from the supports, the weight of the beam being neglected.

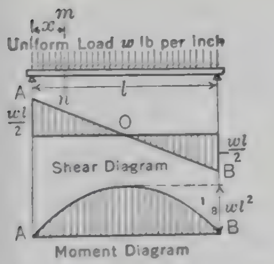

Fig. 14. Shear and moment diagrams, simple beam.

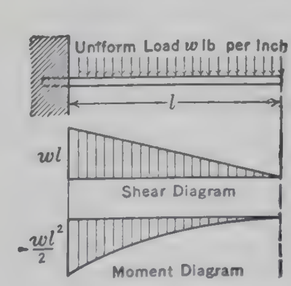

Fig. 15. Shear and moment diagrams, cantilever beam.

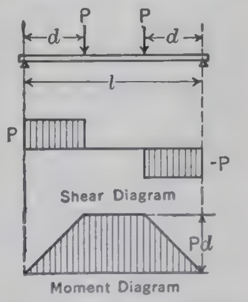

Fig. 16. Shear and moment diagrams, simple beam with two concentrated loads.

Resisting Shear. The tendency of a beam to shear vertically along any cross section, due to the vertical shear, is opposed by an internal shearing stress at that cross section known as the resisting shear; it is equal to the algebraic sum of the vertical components of all the internal stresses acting on the cross section.

If V = vertical shear, pounds; V_r = resisting shear, pounds; τ = average unit shearing stress, pounds per square inch; and A = area of the section, square inches, then at any cross section

$$V_r = V = \tau A; \qquad \tau = \frac{V}{A} \tag{1}$$

The resisting shear is not uniformly distributed over the cross section, but the intensity varies from zero at the extreme fiber to its maximum value at the neutral axis.

At any point in any cross section the vertical unit shearing stress is

$$\tau = \frac{VA'c'}{It} \tag{2}$$

where V = total vertical shear in pounds for section considered; A' = area in square inches of cross section between a horizontal plane through the point where shear is being found and the extreme fiber on the same side of the neutral axis; c' = distance in inches from neutral axis to center of gravity of area A'; I = moment of inertia of the section, inches^4; t = width of section at plane of shear, inches. Maximum value of the unit shearing stress, where A = total area, square inches, of cross section of the beam, is

$$\text{For a solid rectangular beam:}\quad \tau = \frac{3V}{2A} \tag{3}$$

$$\text{For a solid circular beam:}\quad \tau = \frac{4V}{3A} \tag{4}$$

Horizontal Shear. In a beam, at any cross section where there is a vertical shearing force, there must be resultant unit shearing stresses acting on the vertical faces of particles that lie at that section. On a horizontal surface of such a particle, there is a unit shearing stress equal to the unit shearing stress on a vertical surface of the particle. Equation 2, therefore, also gives the horizontal unit shearing stress at any point on the cross-section of a beam.

Bending moment, at any cross section of a beam, is the algebraic sum of the moments of the external forces acting on either side of the section. It is positive when it causes the beam to bend convex downward, hence causing compression in upper fibers and tension in lower fibers of the beam. When the bending moment is determined from the forces that lie to the left of the section, it is positive if it acts in a clockwise direction; if determined from forces on the right side, it is positive if it acts in a counterclockwise direction. If the moments of upward forces are given positive signs, and the moments of downward forces negative signs, the bending moment will always have the correct sign, whether determined from the right or left side. The bending moment should be determined for the side for which the calculation will be simplest.

In Fig. 14 let M be the bending moment, pound-inches, at a section mn of a simple beam at a distance x, inches, from the left support; w = weight of beam per 1 in. of length; l = length of the beam, inches. Then the reactions are $^1/_2\,wl$, and $M = {}^1/_2\,wlx - {}^1/_2\,xwx$. For the sections at the supports, $x = 0$ or l and $M = 0$. For the section at the center of the span $x = {}^1/_2\,l$ and $M = {}^1/_8\,wl^2 = {}^1/_8\,Wl$, where W = total weight.

A moment diagram (Figs. 14, 15, and 16) shows the bending moment at all cross sections of a beam. Ordinates to the curve represent to scale the moments at the corresponding cross sections. The curve for a simple beam uniformly loaded is a parabola, showing $M = 0$ at the supports and $M = {}^1/_8\,wl^2 = {}^1/_8\,Wl$ at the center, M being in pound-inches.

The dangerous section is the cross section of a beam where the bending moment is greatest. In a cantilever beam it is at the point of support, regardless of the disposition of the loads. In a simple beam it is that section where the vertical shear changes from positive to negative, and it may be located graphically by constructing a shear diagram, or numerically by taking the left reaction and subtracting the loads in order from the left until a point is reached where the sum of the loads subtracted equals the reaction. For a simple beam, uniformly loaded, the dangerous section is at the center of the span.

Resisting Moment. The tendency to rotate about a point in any cross section of a beam is due to the bending moment at that section. This tendency is resisted by the resisting moment, which is the algebraic sum of the moments of all the horizontal stresses with reference to the same point.

FORMULA FOR FLEXURE. Let M = bending moment; M_r = resisting moment of the horizontal fiber stresses; σ = unit stress (tensile or compressive) on any fiber, usually that one most remote from the neutral surface; c = distance of that fiber from the neutral surface. Then

$$M = M_r = \frac{\sigma I}{c} \tag{5}$$

$$\sigma = \frac{Mc}{I} \tag{6}$$

where I = moment of inertia of the cross section with respect to its neutral axis. If σ is in pounds per square inch, M must be in pound-inches, I in inches^4, and c in inches.

$r = \dfrac{h}{6(b + b_1)}\sqrt{2(b^2 + 4bb_1 + b_1^2)}$

Equation 6 is the basis of the design and investigation of beams. It is true only when the maximum horizontal fiber stress σ does not exceed the proportional limit of the material.

MOMENT OF INERTIA is the sum of the products of each elementary area of the cross section multiplied by the square of the distance of that area from the assumed axis of rotation, or

$$I = \Sigma r^2 \, \Delta A = \int r^2 \, dA \tag{7}$$

where Σ is the sign of summation, ΔA is an elementary area of the section, and r is the distance of ΔA from the axis. The moment of inertia is greatest in those sections (such as I-beams) having much of the area concentrated at a distance from the axis. Unless otherwise stated, the neutral axis is the axis of rotation considered. I usually is expressed in in.^{4} See Table 1 for values of moments of inertia of various sections.

MODULUS OF RUPTURE is the term applied to the value of σ as found by eq. 6, when a beam is loaded to the point of rupture. Since eq. 6 is true only for stresses within the proportional limit, the value σ of the rupture strength so found is incorrect. However, the equation is used, as a measure of the ultimate load-carrying capacity of a beam. The modulus of rupture does not show the actual stress in the extreme fiber of a beam; it is useful only as a basis of comparison. If the strength of a beam in tension differs from its strength in compression, the modulus of rupture is intermediate between the two.

SECTION MODULUS, the factor I/c in flexure (eq. 5), is expressed in inches^3. It is the measure of a capacity of a section to resist a bending moment. For values of I/c for simple shapes, see Table 1. See Eshbach, *Handbook of Engineering Fundamentals* (John Wiley and Sons) for properties of standard steel and aluminum structural sections.

ELASTIC DEFLECTION OF BEAMS. When a beam bends under load, all points of the elastic curve except those over the supports are deflected from their original positions. The radius of curvature ρ of the elastic curve at any section is expressed as

$$\rho = \frac{EI}{M} \tag{8}$$

where E = modulus of elasticity of the material, pounds per square inch; I = moment of inertia, inches^4, of the cross section with reference to its neutral axis; M = bending moment, pound-inches, at the section considered. Where there is no bending moment, ρ is infinity and the curve is a straight line; where M is greatest, ρ is smallest and the curvature, therefore, is greatest.

If the elastic curve is referred to a system of coordinate axes in which x represents horizontal distances, y vertical distances, and l distances along the curve, the value of ρ is found, by the aid of the calculus, to be $d^3l/dx \cdot d^2y$. Differential eq. 9 of the elastic curve which applies to all beams when the elastic limit of the material is not exceeded is obtained by substituting this value in the expression $\rho = EI/M$ and assuming that dx and dl are practically equal:

$$EI \frac{d^2y}{dx^2} = M \tag{9}$$

Equation 9 is used to determine the deflection of any point of the elastic curve, by regarding the point of support as the origin of the coordinate axis, taking y as the vertical deflection at any point on the curve and x as the horizontal distance from the support to the point considered. The values of E, I, and M are substituted and the expression is integrated twice, giving proper values to the constants of integration, and the deflection y is determined for any point. See Table 2.

For example, the cantilever beam shown in Fig. 12 has a length = l, inches, and carries a load P, pounds, at the free end. It is required to find the deflection of the elastic curve at a point distant x, inches, from the support, the weight of the beam being neglected.

The moment $M = -P(l - x)$. By substitution in eq. 9, the equation for the elastic curve becomes $EI(d^2y/dx^2) = -Pl + Px$. By integrating and determining the constant of integration by the condition that $dy/dx = 0$ when $x = 0$, $EI(dy/dx) = -Plx + {}^1/_2 Px^2$ results. By integrating a second time and determining the constant by the condition that $x = 0$ when $y = 0$, $EIy = -{}^1/_2 Plx^2 + {}^1/_6 Px^3$, which is the equation of the elastic curve, results. When $x = l$, the value of y, or the deflection in inches at the free end, is found to be $-Pl^3/3EI$.

DEFLECTION DUE TO SHEAR. The deflection of a beam as computed by the ordinary formulas is that due to flexural stresses only. In short beams the deflection due to vertical shear sometimes is appreciable and may need to be considered. Because of the nonuniform distribution of the shear over the cross section of the beam, computing the

deflection due to shear by exact methods is difficult. It may be approximated by $y_s = M/AE_s$, where y_s = deflection, inches, due to shear; M = bending moment, pound-inches, at the section where the deflection is calculated; E_s = modulus of elasticity in shear, pounds per square inch; A = area of cross section of beam, square inches. (See Ref. 1, p. 164.) For a rectangular section, the ratio of deflection due to shear, to deflection due to bending, will be less than 5% if the depth of the beam is less than one-eighth of the length.

3. DESIGN OF BEAMS

DESIGN PROCEDURE. In designing a beam the procedure is: (1) Compute reactions. (2) Determine position of the dangerous section and the bending moment at that section. (3) Divide the maximum bending moment (expressed in pound-inches) by the allowable unit stress (expressed in pounds per square inch) to obtain the minimum value of the section modulus. (4) Select a beam section with a section modulus equal to or slightly greater than the section modulus required.

WEB SHEAR. A beam designed in the foregoing manner is safe against rupture of the extreme fibers due to bending in a vertical plane, and usually the cross section will have sufficient area to sustain the shearing stresses with safety. For short beams carrying heavy loads, however, the vertical shear at the supports is large, and it may be necessary to increase the area of the section to keep the unit shearing stress within the limit allowed. For steel beams, the average unit shearing stress is computed by $\tau = V/A$, where V = total vertical shear, pounds; A = area of web, square inches.

MISCELLANEOUS CONSIDERATIONS. Other considerations which will influence the choice of section under certain conditions of loading are: (1) Maximum vertical deflection that may be permitted in beams coming in contact with plaster. (2) Danger of failure by sidewise bending in long beams, unbraced against lateral deflection. (3) Danger of failure by the buckling of the web of steel beams of short span carrying heavy loads. (4) Danger of failure by horizontal shear, particularly in wooden beams.

VERTICAL DEFLECTION. If a beam is to support or come in contact with materials like plaster, which may be broken by excessive deflection, it is usual to select such a beam that the maximum deflection will not exceed ($^1/_{360}$ × span). It may be shown that for a simple beam, supported at the ends, with a total uniformly distributed load W, pounds, the deflection, inches, is

$$y = \frac{30\sigma L^2}{Ed} \tag{10}$$

where σ = allowable unit fiber stress, pounds per square inch; L = span of beam, feet; E = modulus of elasticity, pounds per square inch; d = depth of beam, inches.

If the deflection of a steel beam is to be less than $^1/_{360}$ of the span, it may be shown from eq. 10 that, for a maximum allowable fiber stress of 18,000 psi, the limit of span in feet is approximately $1.8d$, where d = depth of the beam, inches.

For the deflection due to the impact of a moving load falling on a beam, see p. 8-40.

HORIZONTAL SHEAR IN TIMBER BEAMS. In beams of a homogeneous material which can withstand equally well shearing stresses in any direction, vertical and horizontal shearing stresses are equally important. In timber, however, shearing strength along the grain is much less than that perpendicular to the grain. Hence, the beams may fail owing to horizontal shear. Short wooden beams should be checked for horizontal shear in order that allowable unit shearing stress along the grain shall not be exceeded. (See Example below.)

RESTRAINED BEAMS. A beam is considered to be restrained if one or both ends are not free to rotate. This condition exists if a beam is built into a masonry wall at one or both ends, if it is riveted or otherwise fastened to a column, or if the ends projecting beyond the supports carry loads which tend to prevent tilting of the ends which would naturally occur as the beam deflects. The shears and moments given in Table 2 for fixed end conditions are seldom, if ever, attained, since the restraining elements themselves deform and and reduce the magnitude of the restraint. This reduction of restraint decreases the negative moment at the support and increases the positive moment in the central portion of the span. The amount of restraint which exists is a matter which must be judged for each case in the light of the construction used, the rigidity of the connections, and the relative sizes of the connecting members.

SAFE LOADS ON SIMPLE BEAMS. Equation 11 gives the safe loads on simple beams. This formula is obtained by substituting in the flexure eq. 5, the value of M for a simple beam, uniformly loaded, as given in Table 2. Let W = total load, pounds; σ = extreme fiber unit stress, pounds per square inch; S = section modulus, inches^3; L = length of span, feet. Then

$$W = \frac{2}{3}\sigma\frac{S}{L} \tag{11}$$

If σ is taken as a maximum allowable unit fiber stress, this equation gives the maximum allowable load on the beam. Most building codes permit a value of σ = 18,000 psi for quiescent loads on steel. For this value of σ, eq. 11 becomes

$$W = \frac{12{,}000\ S}{L} \tag{12}$$

If the load is concentrated at the center of the span, the safe load is one-half the value given by eq. 12. If the load is neither uniformly distributed nor concentrated at the center of the span, the maximum bending moment must be used. The foregoing equations are for beams laterally supported and are for flexure only. The other factors which influence the strength of the beam, as shearing, buckling, etc., must also be considered.

* The sections of the beams near the ends must be increased over the amounts shown to resist the vertical shear expressed by the formula $\sigma = 3/2\ V/A$.

USE OF TABLES IN DESIGN. The following is an example in the use of tables for the design of a wooden beam.

Example. Design a southern pine girder, of common structural grade, to carry a load of 9600 lb distributed uniformly over a 16-ft span in the interior of a building, the beam being a simple beam, freely supported at each end.

Solution. From Table 2, the bending moment of a simple beam uniformly loaded is $M = wl^2/8$. Since $W = wl$ and $l = 12L$,

$$M = 9600 \times 16 \times 12/8 = 230{,}400 \text{ lb-in.}$$

If the allowable unit stress on yellow pine is 1200 psi,

$$\frac{I}{c} = \frac{230{,}400}{1200} = 192 \text{ in.}^3$$

From Table 1, the section modulus of a rectangular section is $bd^2/6$. Assume $b = 8$ in. Then $8d^2/6 = 192$, and $d = \sqrt{144} = 12.0$ in. A beam 8 by 12 in. is selected tentatively, and checked for shear.

Maximum shearing stress (horizontal and vertical) is at the neutral surface over the supports. Equation 3 for horizontal shear in a solid rectangular beam is $\tau = 3V/2A$; $V = 9600/2 = 4800$, and $A = 8 \times 12 = 96$, whence $\tau = (3 \times 4800)/(2 \times 96) = 75$ psi.

If the safe horizontal unit shearing stress for common-grade southern yellow pine is 88 psi, and since the actual horizontal unit shearing stress is less than 88 lb, the 8 by 12 in. beam will be satisfactory.

A BEAM OF UNIFORM STRENGTH is one in which the dimensions are such that the maximum fiber stress σ is the same throughout the length of the beam. The form of the beam is determined by finding the areas of various cross sections from the flexure formula $M = \sigma I/c$, keeping σ constant and making I/c vary with M. For a rectangular section of width b and depth d, the section modulus $I/c = {}^1/_6\, bd^2$, and, therefore, $M = {}^1/_6\, \sigma bd^2$. By making bd^2 vary with M, the dimensions of the various sections are obtained. Table 3 gives the dimensions b and d, at any section, the maximum unit fiber stress σ and the maximum deflection y, of some rectangular beams of uniform strength. In this table, the bending moment has been assumed to be the controlling factor. On account of the vertical shear near the ends of the beams, the area of the sections must be increased over that given by an amount necessary to keep the unit shearing stress within the allowable unit shearing stress. The discussion of beams of uniform strength, though of considerable theoretical interest, is of little practical value since the cost of fabrication will offset any economy in the use of the material. A plate girder in a bridge or a building is an approximation in practice to a steel beam of uniform strength.

4. CONTINUOUS BEAMS

As in simple beams, the expressions $M = \sigma I/c$ and $\tau = V/A$ govern the design and investigation of beams resting on more than two supports. In the case of continuous beams, however, the reactions cannot be obtained in the manner described for simple beams. Instead, the bending moments at the various sections must be determined, and from these values the vertical shears at the sections and the reactions at the supports may be derived.

Consider the second span of length l_2, inches, of the continuous beam (Fig. 17). Vertical shear V_x at any section distant x, inches, from the left support of the span is equal to the algebraic sum of all the vertical forces on one side of the section. Thus, if V_2 = vertical shear at a section to the right of, but infinitely close to, the left support, w_2x = uniform load, and ΣP_2 = sum of the concentrated loads along the distance x, applied at a distance kl_2 from the left support, k being a fraction less than unity, then

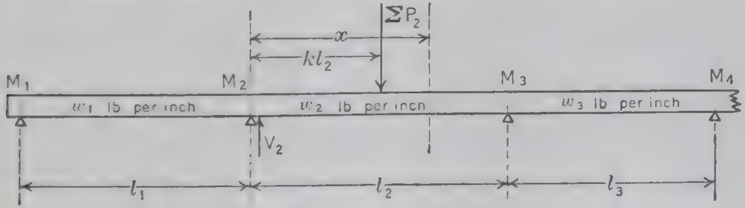

FIG. 17. Continuous beam.

$$V_x = V_2 - w_2x - \Sigma P_2 \tag{13}$$

At any section, distant x from the left support, the bending moment is equal to the algebraic sum of the moments of all forces on one side of the section. If M_2 is the moment, pound-inches, at the support to the left,

$$M_x = M_2 + V_2x - \frac{w_2x^2}{2} - \Sigma P_2(x - kl_2) \tag{14}$$

Assume that $x = l_2$. Then M_x becomes the moment M_3 at the next support to the right, and the expression may be written

$$V_2l_2 = M_3 - M_2 + \frac{w_2l_2^2}{2} + \Sigma P_2(l_2 - kl_2) \tag{15}$$

From eqs. 13, 14, and 15 it is evident that the bending moment M_x and the shear V_x at any section between two consecutive supports may be determined if the bending moments M_2 and M_3 at those supports are known.

To determine bending moments at the supports an expression known as the *theorem of three moments* is used. This gives the relation between the moments at any three consecutive supports of a beam. For beams with the supports on the same level, and uniformly loaded over each span, the formula is

$$M_1 l_1 + 2M_2(l_1 + l_2) + M_3 l_2 = -{}^1\!/_4\, w_1 l_1^3 - {}^1\!/_4\, w_2 l_2^3 \tag{16}$$

where M_1, M_2, and M_3 = moments of three consecutive supports; l_1 = length between first and second support; l_2 = length between second and third support; w_1 = uniform load per lineal unit over the first span, w_2 = uniform load per lineal unit over the second span. When both spans are of equal length and when the load on each span is the same, $l_1 = l_2$, $w_1 = w_2$, and eq. 16 reduces to

$$M_1 + 4M_2 + M_3 = -{}^1\!/_2\, wl^2 \tag{17}$$

which applies to most cases in practice.

Equations 16 and 17 are used as follows: For any continuous beam of n spans there are $(n + 1)$ supports. Assuming the ends of the beam to be simply supported without any overhang, the moments at the end supports are zero, and there are, therefore, to be determined $(n - 1)$ moments at the other supports. This may be done by writing $(n - 1)$ equations of the form of eqs. 16 and 17 for each support. These equations will contain $(n - 1)$ unknown moments, and their solution will give values of M_1, M_2, M_3, etc., expressed as coefficients of wl^2. The shear V_1 at any support may be determined by substituting values of M_1 and M_2 in eq. 15, and the bending moment at any point in any span may be obtained by eq. 14. The shear at any point in any span may be determined from eq. 13.

FIG. 18. Shear and moment diagrams of continuous beams.

Figure 18 gives values and diagrams for the reactions, shears, and moments at all sections of continuous beams uniformly loaded up to five spans. Note that the reaction at any support is equal to the sum of the shears to the right and to the left of that support.

5. AXIALLY END-LOADED BEAMS *

DEFLECTION OF BEAM NEGLIGIBLE. When a beam is subjected to an axial end load as well as to a transverse bending load, the resultant unit stress developed at any point in the beam is the algebraic sum of the unit stresses produced by each of the loads acting independently of each other. If the beam of cross-sectional area A, square inches, is considered so short that its deflection under load may be neglected, the unit stress produced at any cross section of the beam by an axial load P, pounds, is P/A. The maximum unit stress (tensile or compressive), pounds per square inch, due to the transverse or bending load is given by $\sigma = M/(I/c)$, where M, pound-inches, is the maximum bending moment due to this load; I, inches^4, is the moment of inertia of the cross section with respect to the neutral axis; c, inches, is the distance from the neutral axis to the extreme fiber. If the axial load is compressive, the maximum unit stress is compressive, occurring at the top of the beam, and is

$$\sigma = \frac{P}{A} + \frac{Mc}{I} \tag{18}$$

The unit stress on the bottom fiber may be either tensile or compressive, according as Mc/I is larger or smaller than P/A. If the longitudinal load P were a tensile load, the maximum unit stress would occur on the bottom fiber and would be a tensile stress.

DEFLECTION OF BEAM NOT NEGLIGIBLE. If the deflection of the beam is not negligible, the load P cannot be considered an axial load with respect to any cross sections except the end sections. The longitudinal load then has a moment arm equal to the deflection, and the stress due to this moment should be added algebraically to that caused by the other moments or loads. The stress due to deflection, y, inches (all other symbols as above), is Pyc/I. Thus, for a compressive longitudinal load, the maximum unit stress, pounds per square inch, is at the top of the beam and is

$$\sigma = \frac{P}{A} + \left(M + Py\right)\frac{c}{I} \tag{19}$$

Unit tensile stress, pounds per square inch, at the bottom of the beam for the same load is

$$\sigma = -\frac{P}{A} + \left(M + Py\right)\frac{c}{I} \tag{20}$$

Since the value of y depends on the total bending moment $(M + Py)$, and the bending moment depends, in turn, on the value of y, eqs. 19 and 20 usually are solved by a method of approximation. The value of y that would be caused by the cross-bending moment M, considered acting alone, is found first, and then is used in the expression, $M + Py$. This new value of the total bending moment is used to find a closer approximation to y. This operation may be repeated as many times as desired. When the deflection is small, as in comparatively short beams, the value of y as found from the cross-bending moment above often is used without any further approximation.

Example. Find the stress at the bottom and at the top of a timber beam 6 in. wide, 8 in. deep, and 12 ft long, supported at each end, and carrying a distributed load of 400 lb per ft, and also an axial compressive load of 10,000 lb. The modulus of elasticity of the timber may be taken as 1,600,000.

Solution. Maximum unit stress will be at the center of the beam.

$$\frac{P}{A} = \frac{10{,}000}{48} = 208 \text{ psi}$$

$$\frac{Mc}{I} = \frac{400 \times 12 \times 144}{8} \times \frac{6}{6 \times 8^2} = 1350 \text{ psi}$$

See Table 2, p. 8-12.

$$y = \frac{5 \times 4800 \times 144^3 \times 12}{384 \times 6 \times 8^3 \times 1{,}600{,}000} = 0.456 \text{ in.}$$

$$\frac{Pyc}{I} = \frac{10{,}000 \times 0.456 \times 6}{6 \times 8^2} = 71 \text{ psi}$$

Total unit compressive stress (top) = 208 + 1350 + 71 = 1629 psi.

Total unit tensile stress (bottom) = −208 + 1350 + 71 = 1213 psi.

Here the stress due to deflection is small, as it usually will be in short deep beams.

---

* Y_0 is distance from centroidal axis to neutral axis, where beam is subjected to pure bending.

6. CURVED BEAMS

The derivation of the flexure formula, $\sigma = Mc/I$, assumes that the beam is initially straight; therefore, any deviation from this condition introduces an error in the value of the stress. If the curvature is slight the error involved is not large, but in beams with a large amount of curvature, as hooks, chain links, and frames of punch presses, the error involved in the use of the ordinary flexure formula is considerable. The effect of the curvature is to increase the stress in the inside and to decrease it on the outside fibers of the beam and to shift the position of the neutral axis from the centroidal axis toward the concave or inner side.

The correct value for the unit fiber stress may be found by introducing a correction factor in the flexure formula, $\sigma = KMc/I$; the factor K depends on the shape of the beam and on the ratio R/c, where R = distance, inches, from the centroidal axis of the section to the center of curvature of the central axis of the unstressed beam; and c = distance, inches, of centroidal axis from the extreme fiber on the inner or concave side. Reference 2 has an analysis of curved beams as does Table 4, which gives values of K for a number of shapes and ratios of R/c. For slightly different shapes or proportions K may be found by interpolation.

7. COLUMNS—DEFINITIONS

A COLUMN OR STRUT is a bar or structural member under axial compression, which has an unbraced length greater than about eight or ten times the least dimension of its cross section. On account of its length, it is impossible to hold a column in a straight line under a load; a slight sidewise bending always occurs, causing flexural stresses in addition to the compressive stresses induced directly by the load. The lateral deflection will be in a direction perpendicular to that axis of the cross section about which the moment of inertia is the least. Thus in Fig. 19*A* the column will bend in a direction perpendicular to *aa*, in Fig. 19*B* it will bend perpendicular to *aa* or *bb*, and in Fig. 19*C* it is likely to bend in any direction.

RADIUS OF GYRATION of a section with respect to a given axis is equal to the square root of the quotient of the moment of inertia with respect to that axis, divided by the area of the section, that is

$$k = \sqrt{\frac{I}{A}}; \qquad \frac{I}{A} = k^2 \tag{21}$$

where I is the moment of inertia and A the sectional area. Unless otherwise mentioned, an axis through the center of gravity of the section is the axis considered. As in beams, the moment of inertia is an important factor in the ability of the column to resist bending, but for purposes of computation it is more convenient to use the radius of gyration.

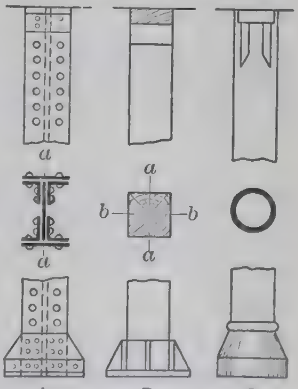

FIG. 19. Column end designs.

LENGTH OF A COLUMN is the distance between points unsupported against lateral deflection.

SLENDERNESS RATIO is the length l divided by the least radius of gyration k, both in inches. For steel, a *short column* is one in which $l/k < 20$ or 30, and its failure under load is due mainly to direct compression; in a *medium-length column*, l/k = about 30 to 175, and it will fail by a combination of direct compression and bending; in a *long column*, $l/k >$ about 175 to 200, and it will fail mainly by bending. For timber columns these ratios are about 0 to 30, 30 to 90, and above 90 respectively. The load which will cause a column to fail decreases as l/k increases. The above ratios apply to round-end columns. If the ends are fixed (see below), the effective slenderness ratio is one-half that for round-end columns, as the distance between the points of inflection is one-half the total length of the column. For flat ends it is intermediate between the two.

CONDITIONS OF ENDS. The various conditions which may exist at the ends of columns usually are divided into four classes: (1) Columns with round ends; the bearing at either end has perfect freedom of motion, as there would be with a ball-and-socket joint at each end. (2) Columns with hinged ends; they have perfect freedom of motion at the ends in one plane, as in compression members in bridge trusses where loads are transmitted through end pins. (3) Columns with flat ends; the bearing surface is normal to the axis of the column and of sufficient area to give at least partial fixity to the ends of the columns against lateral deflection. (4) Columns with fixed ends; the ends are rigidly secured, so that under any load the tangent to the elastic curve at the ends will be parallel to the axis in its original position.

Experiments prove that columns with fixed ends are stronger than columns with flat, hinged, or round ends, and that columns with round ends are weaker than any of the other types. Columns with hinged ends are equivalent to those with round ends in the plane in which they have free movement, columns with flat ends have a value intermediate between those with fixed ends and those with round ends. It often happens that columns have one end fixed and one end hinged, or some other combination. Their relative values may be taken as intermediate between those represented by the condition at either end. The extent to which strength is increased by fixing the ends depends on the length of column, fixed ends having a greater effect on long columns than on short ones.

8. THEORY OF COLUMNS

There is no exact theoretical formula which gives the strength of a column of any length under an axial load. Formulas involving the use of empirical coefficients have been deduced, however, and they give results which are consistent with the results of tests of full-sized members.

EULER'S FORMULA assumes that the failure of a column is due solely to the stresses induced by sidewise bending. This assumption is not true for very short columns, which fail mainly by direct compression, nor is it true for columns of medium length. The failure in such cases is by a combination of direct compression and bending. For columns in which $l/k > 200$, Euler's formula is approximately correct and agrees closely with the results of tests.

Let P = axial load, pounds; l = length of column, inches; I = least moment of inertia, inches^4; k = least radius of gyration, inches; E = modulus of elasticity; y = lateral deflection, inches, at any point along the column, that is caused by load P. If a column has round ends, so that the bending is not restrained, the equation of its elastic curve is

$$EI \frac{d^2y}{dx^2} = -Py \tag{22}$$

when the origin of the coordinate axes is at the top of the column, the positive direction of x being taken downwards and the positive direction of y in the direction of the deflection. Integrating the above expression twice and determining the constants of integration give

$$P = \Omega\pi^2 \frac{EI}{l^2} \tag{23}$$

which is Euler's formula for long columns. The factor Ω is a constant depending on the condition of the ends. For round ends $\Omega = 1$; for fixed ends $\Omega = 4$; for one end round and the other fixed $\Omega = 2.05$. P is the load at which, if a slight deflection is produced, the column will not return to its original position. If P is decreased the column will approach its original position, but if P is increased the deflection will increase until the column fails by bending.

For columns with value of l/k less than about 150, Euler's formula gives results distinctly higher than those observed in tests. Euler's formula is now little used except for long members and as a basis for the analysis of the stresses in some types of structural and machine parts. It always gives an *ultimate* and never an allowable load.

SECANT FORMULA. The deflection of the column is used in the derivation of the Euler formula, but if the load were truly axial it would be impossible to compute the deflection. If the column is assumed to have an initial eccentricity of load of e in. (see Ref. 1, p. 241, for suggested values of e), the equation for the deflection y becomes

$$y_{\max} = e\left(\sec \frac{l}{2}\sqrt{\frac{P}{EI}} - 1\right) \tag{24}$$

The maximum unit compressive stress becomes

$$\sigma = \frac{P}{A}\left(1 + \frac{ec}{k^2}\sec \frac{l}{2}\sqrt{\frac{P}{EI}}\right) \tag{25}$$

where l = length of column, inches; P = total load, pounds; A = area, square inches; I = moment of inertia, inches^4; k = radius of gyration, inches; c = distance from neutral axis to the most compressed fiber, inches; E = modulus of elasticity; both I and k are taken with respect to the axis about which bending takes place. Because the formula contains the secant of the angle $(l/2)\sqrt{P/EI}$ it is sometimes called the *secant formula*. It has been suggested by the Committee on Steel-Column Research (Ref. 3) that the best rational column formula can be constructed on the secant type, though of course it must contain experimental constants.

The secant formula can be used also for columns that are eccentrically loaded, if e is taken as the actual eccentricity plus the assumed initial eccentricity.

RANKINE'S FORMULA is a modification of an earlier formula by Gordon, and sometimes is called Gordon's formula. It applies to columns of slenderness ratios of 20 to 200, which are usually required in practice. Rankine's formula assumes that the maximum unit stress, σ, pounds per square inch, occurs in the fiber most remote from the axis on the concave side of the deflected column, and is equal to the sum of the direct unit compressive stress and the unit compressive stress due to bending alone; that is, $\sigma = (P/A) + \sigma_1$ where P = load, pounds; A = sectional area, square inches; σ_1 = unit compressive stress due to bending, pounds per square inch. The value of σ_1 in this equation may be expressed in terms of P by using the flexure formula, since the action is analogous to that of beams. Let l = length of the column, inches; I = least moment of inertia, inches^4; k = corresponding radius of gyration, inches; c = distance from axis to the remotest fiber on the concave side, inches; y = lateral deflection of column, inches. Substituting in the flexure formula, $\sigma_1 = Mc/I$, and by replacing M by its value Py and I by its value Ak^2, $\sigma_1 = Pyc/(Ak^2)$. Hence maximum unit compressive stress on the remotest fiber on the concave side is equal to $P/A + Pyc/(Ak^2)$. By analogy with the theory of beams the deflection y varies as l^2/c, so that by introducing an experimental coefficient ϕ, the expression for maximum unit stress may be written

$$\sigma = \frac{P}{A} + \phi\frac{Pl^2}{Ak^2} = \frac{P}{A}\left[1 + \phi\left(\frac{l}{k}\right)^2\right] \tag{26}$$

which is Rankine's formula for the investigation of columns. Variations in the value of ϕ have been determined by many experiments on columns of different materials and different conditions of ends. For further information see Ref. 1, p. 221.

The value to be taken for σ in Rankine's formula is the ultimate compressive stress of the material for rupture, and the allowable compressive unit stress for design. Rankine's formula may be used in the investigation of an existing column by comparing the computed value of σ with the proportional limit and with the ultimate strength of the material, thus determining the factor of safety. Similarly, the safe load P for an existing column may be computed by assuming an allowable unit stress σ.

STRAIGHT-LINE FORMULA. Plotted results of actual tests on columns show that the relation between ultimate load and l/k is fairly well represented by a straight line, for columns which fail by flexure of the whole column and not by local collapse. For a value of $l/k = 0$, average unit stress, P/A, on the section, is equal to the ultimate stress in compression for brittle materials and to the yield point in compression for ductile materials. From the point thus determined the straight line representing the average results of tests is drawn tangent to the curve of Euler's formula for the material. The equation of the straight line is

$$\frac{P}{A} = \sigma - \frac{Cl}{k} \tag{27}$$

where σ = ultimate unit stress in compression for a brittle material, or unit stress at the yield point in compression for a ductile material; C = an experimental constant. Table 5 gives average values of σ and C for structural steel, cast iron, and wood. The loads given

Table 5. Ultimate Strength Constants for the Straight-line Column Formula

Material	σ_1 psi	Character of Ends					
		Round	Fixed	1 round 1 fixed	Round	Fixed	1 round 1 fixed
		C			Limit of (l/k)		
Structural steel	35,000	150	75	100	160	320	240
Cast iron	34,000 *	175	88	116	90	160	115
Wood	5,000 *	40	20	30	75	150	112

* This is less than the ultimate in compression for small specimens of cast iron or wood, but from tests of full-size columns it seems to be the value to be used for full-size castings or timbers which may contain defects. See Timoshenko, *Theory of Elastic Stability*, Chapter III, McGraw-Hill Book Co., for further information.

by the straight-line formula using the constants in this table are *ultimate loads*. For design the straight-line formula usually is put in a form which gives allowable loads directly, constants σ and C being divided by a factor of safety. The straight-line formula is not suitable for investigating a column, i.e., determining values of σ due to given loads, as C/k is not a function of (P/A). It may be used to find the safe load for a given column under a given unit stress or to design a column for a given load and unit stress.

ECCENTRIC LOADS ON SHORT COMPRESSION MEMBERS. Where a direct push acting on a member does not pass through the centroid but at a distance e, inches, from it, both direct and bending stresses are produced. For short compression members in which column action may be neglected, the direct unit stress is P/A, where P = total load, pounds, and A = area of cross section, square inches. The bending unit stress is Mc/I, where $M = Pe$ = bending moment, pound-inches; c = distance, inches, from the centroid to the fiber in which the stress is desired, I = moment of inertia, inches^4. The total unit stress at any point in the section is $\sigma = P/A + Pec/I$, or $\sigma = (P/A)(1 + ec/k^2)$, since $I = Ak^2$, where k = radius of gyration, inches.

ECCENTRIC LOADS ON COLUMNS. Various column formulas must be modified when the loads are not balanced, that is, when the resultant of the loads is not in line with the axis of the column. If P = load, pounds, applied at a distance e in. from the axis, bending moment $M = Pe$. Maximum unit stress σ, pounds per square inch, due to this bending moment alone, is $\sigma = Mc/I = Pec/Ak^2$, where c = distance, inches, from the axis to the most remote fiber on the concave side; A = sectional area in square inches; k = radius of gyration in the direction of the bending, inches. This unit stress must be added to the unit stress that would be induced if the resultant load were applied in line with the axis of the column. The modified formulas, expressed in allowable load per unit of area, are:

Modified Rankine's formula for eccentric loads (see p. 8-23)

$$\frac{P}{A} = \frac{\sigma}{1 + \phi\left(\frac{l}{k}\right)^2 + \frac{ec}{k^2}} \tag{28}$$

Modified straight-line formula for eccentric loads (see p. 8-23):

$$\frac{P}{A} = \frac{\sigma - \frac{Cl}{k}}{1 + \frac{ec}{k^2}} \tag{29}$$

The secant formula, p. 8-22, also can be used for columns that are eccentrically loaded if e is taken as the actual eccentricity plus the assumed initial eccentricity.

COLUMN SUBJECTED TO TRANSVERSE OR CROSS-BENDING LOADS. A compression member that is subjected to cross-bending loads may be considered to be (1) a beam subjected to end thrust as discussed on p. 8-19 or (2) a column subjected to cross-bending loads, depending on the relative magnitude of the end thrust and cross-bending loads, and on the dimensions of the member. The various column formulas may be modified so as to include the effect of cross-bending loads. In this form they are:

Modified Rankine's formula for transverse loads:

$$\sigma = \frac{P}{A}\left(1 + \phi\frac{l^2}{k^2}\right) + \frac{Pyc}{Ak^2} + \frac{Mc}{Ak^2} \tag{30}$$

Modified straight-line formula for transverse loads:

$$\frac{P}{A} = \sigma - \frac{Cl}{k} - \frac{Pyc}{Ak^2} - \frac{Mc}{Ak^2} \tag{31}$$

Modified secant formula for transverse loads:

$$\sigma = \frac{P}{A}\left[1 + (e + y)\frac{c}{k^2}\sec\frac{l}{2k}\sqrt{\frac{P}{AE}}\right] + \frac{Mc}{Ak^2} \tag{32}$$

In these formulas, σ = maximum unit stress on concave side, pounds per square inch; P = axial end load, pounds; A = cross-sectional area, square inches; M = moment due to cross-bending load, pound-inches; y = deflection due to cross-bending load, inches; k = radius of gyration, inches; l = length of column, inches; e = assumed initial eccentricity, inches; c = distance, inches, from axis to the most remote fiber on the concave side; C = experimental constant (see Table 5). The modified straight-line formula, like the straight-line formula, cannot be used to solve for σ.

9. WOODEN COLUMNS

WOODEN COLUMN FORMULAS. One of the principal formulas is that formerly used by the AREA, $P/A = \sigma_1(1 - l/60d)$, where P/A = allowable unit load, pounds per square inch; σ_1 = allowable unit stress in direct compression on short blocks, pounds per square inch; l = length, inches; d = least dimension, inches. This formula is being replaced rapidly by formulas recommended by the ASTM and AREA. Committees of these societies, working with the U. S. Forest Products Laboratory, classified timber columns in three groups (ASTM Standards, 1937, D245-37):

1. Short Columns. The ratio of unsupported length to least dimension does not exceed 11. For these columns, the allowable unit stress should not be greater than the values given in Table 2, p. 5-84, under compression parallel to the grain.

2. Intermediate-length Columns. Where the ratio of unsupported length to least dimension is greater than 10, eq. 33, of the fourth power parabolic type, shall be used to determine allowable unit stress, until this allowable unit stress is equal to two-thirds of the allowable unit stress for short columns.

$$\frac{P}{A} = \sigma_1\left[1 - \frac{1}{3}\left(\frac{l}{Kd}\right)^4\right] \tag{33}$$

where P = total load, pounds; A = area, square inches; σ_1 = allowable unit compressive stress parallel to grain, lb per sq inch (see Table 2, p. 5-84); l = unsupported length, inches; d = least dimension, inches; $K = l/d$ at the point of tangency of the parabolic and Euler curves, at which $P/A = {}^2/_3\,\sigma_1$. The value of K for any species and grade is $(\pi/2\sqrt{E/6\sigma_1})$, where E = modulus of elasticity.

3. Long Columns. Where P/A as computed by eq. 33 is less than ${}^2/_3\,\sigma_1$, eq. 34 of the Euler type, which includes a factor of safety of 3, shall be used:

$$\frac{P}{A} = \frac{1}{36}\left[\frac{\pi^2 E}{(l/d)^2}\right] \tag{34}$$

Timber columns should be limited to a ratio of l/d equal to 50. No higher loads are allowed for square-ended columns. The strength of round columns may be considered the same as that of square columns of the same cross-sectional area.

USE OF TIMBER COLUMN FORMULAS. The values of E (modulus of elasticity) and σ_1 (compression parallel to grain) in the above formulas are given in Table 2, p. 5-84. Table 6 gives the computed values of K for some common types of timbers. These may be substituted directly in eq. 33 for intermediate-length columns, or may be used in conjunction with Table 7, which gives the strength of columns of intermediate length, expressed as a percentage of strength (σ_1) of short columns. In the tables, the term "continuously dry" refers to interior construction where there is no excessive dampness or humidity; "occasionally wet but quickly dry" refers to bridges, trestles, bleachers, and grandstands; "usually wet" refers to timber in contact with the earth or exposed to waves or tidewater.

Table 6. Values of *K* for Columns of Intermediate Length

ASTM Standards, 1937, D245–37

Species	Continuously Dry		Occasionally Wet		Usually Wet	
	Select	Common	Select	Common	Select	Common

Note. This table can also be used for columns not rectangular, the l/d being equivalent to $0.289l/k$, where k is the least radius of gyration of the section.

10. STEEL COLUMNS

TYPES. Two general types of steel columns are in use: (1) rolled shapes; (2) built-up sections. The rolled shapes are easily fabricated, accessible for painting, neat in appearance where they are not covered, and convenient in making connections. A disadvantage is the probability that thick sections are of lower-strength material than thin sections because of the difficulty of adequately rolling the thick material. For the effect of thickness of material on yield point, see Ref. 3, p. 1377.

GENERAL PRINCIPLES IN DESIGN. The design of steel columns is always a cut-and-try method, as no law governs the relation between area and radius of gyration of the section. A column of given area is selected, and the amount of load that it will carry is computed by the proper formula. If the allowable load so computed is less than that to be carried, a larger column is selected and the load for it computed, the process being repeated until a proper section is found.

A few general principles should guide in proportioning columns. The radius of gyration should be approximately the same in the two directions at right angles to each other; the slenderness ratio of the separate parts of the column should not be greater than that of the column as a whole; the different parts should be adequately connected in order that the column may function as a single unit; the material should be distributed as far as possible from the center line in order to increase the radius of gyration.

STEEL COLUMN FORMULAS. A variety of steel column formulas are in use, differing mostly in the value of unit stress allowed with various values of l/k. See Ref. 4, p. 5-42, for a summary of the several formulas.

TESTS ON STEEL COLUMNS. After the collapse of the Quebec Bridge in 1907 as a result of a column failure, the ASCE, the AREA, and the U. S. Bureau of Standards cooperated in tests of full-size steel columns. The results of these tests are reported in Ref. 5, pp. 1583–1688, and are summarized in Ref. 4, pp. 5-43, 5-44. The tests showed that, for columns of the proportions commonly used, the effect of variation in the steel, kinks, initial stresses, and similar defects in the column was more important than the effect of length. They also showed that the thin metal gave definitely higher strength, per unit area, than the thicker metal of the same type of section.

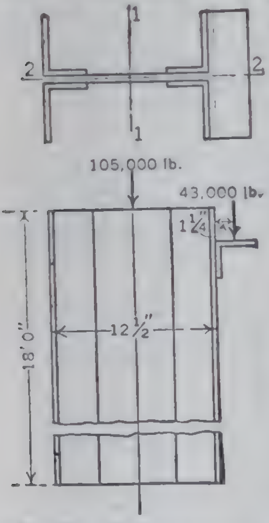

FIG. 20. Built-up column.

EXAMPLE. Design a steel column 18 ft long to carry an axial load of 105,000 lb and an additional load of 43,000 lb which comes from a crane runway, and which is 1¼ in. beyond the outside edge of the column.

The formula used will be the AISC formula (see Ref. 4),

$$\frac{P}{A} = \frac{18{,}000}{1 + \left(\dfrac{l^2}{18{,}000k^2}\right)}$$

The shape selected will be a plate and four angles, Fig. 20.

Using 10,000 psi as a preliminary estimate for the first selection, one plate 12 × 5/16 in. and four angles 5 × 3 1/2 × 3/8 in. will have an area of 15.95 sq in. The safe load for this column will now be found. The moment of inertia I_{1-1} is 412 in.^{4}, the radius of gyration k_{1-1} is 5.08 in., and the radius of gyration k_{2-2} is 2.08 in.

Considering the safe load with respect to axis 2-2 about which neither load is eccentric,

$$P = \frac{15.95 \times 18{,}000}{1 + \dfrac{(18 \times 12)^2}{18{,}000 \times (2.08)^2}} = 179{,}400 \text{ lb}$$

Consider now the safe load about axis 1–1, with respect to which the load of 105,000 lb is axial, and the load of 43,000 lb has an eccentricity of 7 1/2 in. The load of 43,000 lb will produce a stress due to its eccentricity, and this stress will reduce by that amount the unit load that the column can carry. The safe load will therefore be

$$P = 15.95\left(\frac{18{,}000}{1 + \dfrac{(18 \times 12)^2}{18{,}000 \times (5.08)^2}} - \frac{43{,}000 \times 7.5 \times 6.25}{412}\right) = 183{,}000 \text{ lb}$$

The area exceeds that needed by about 3 sq in.; the next smaller size is one plate 12 × 5/16 in. and four angles 5 × 3 1/2 × 5/16 in. The area is 13.99 sq in., moment of inertia, $I_{1-1} = 356$ in.^{4}, $k_{1-1} = 5.04$ in., and $k_{2-2} = 2.03$ in. With respect to the axis 2–2,

$$P = \frac{13.99 \times 18{,}000}{1 + \dfrac{(18 \times 12)^2}{18{,}000 \times (2.03)^2}} = 154{,}600 \text{ lb}$$

With respect to axis 1–1,

$$P = 13.99\left(\frac{18{,}000}{1 + \dfrac{(18 \times 12)^2}{18{,}000 \times (5.04)^2}} - \frac{43{,}000 \times 7.5 \times 6.25}{356}\right) = 149{,}300 \text{ lb}$$

As the load to be carried is 148,000 lb this column is satisfactory.

11. SHAFTS—DEFINITIONS

TORSIONAL STRESS. A bar is under torsional stress when it is held fast at one end, and a force acts at the other end to twist the bar. In a round bar (Fig. 21) with a constant force acting, the straight line *ab* becomes the helix *ad*, and a radial line in the cross section, *ob*, moves to the position *od*. The angle *bad* remains constant while the angle *bod* increases with the length of the bar. Each cross section of the bar tends to shear off the one adjacent to it, and in any cross section the shearing stress at any point is normal to a radial line drawn through the point. Within the shearing proportional limit, a radial line of the cross section remains straight after the twisting force has been applied, and the unit shearing stress at any point is proportional to its distance from the axis.

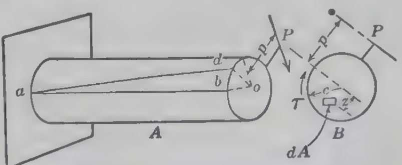

FIG. 21. Round bar subject to torsional stress.

TWISTING MOMENT, T, is equal to the product of the resultant, P, of the twisting forces, multiplied by its distance from the axis, p.

RESISTING MOMENT, T_r, in torsion, is equal to the sum of the moments of the unit shearing stresses acting along a cross section with respect to the axis of the bar. If dA is an elementary area of the section at a distance of z units from the axis of a circular shaft (Fig. 21*B*), and c is the distance from the axis to the outside of the cross section where the unit shearing stress is τ, then the unit shearing stress acting on dA is $(\tau z/c)\,dA$, its moment with respect to the axis is $(\tau z^2/c)\,dA$, and the sum of all the moments of the unit shearing stresses on the cross section is $\int (\tau z^2/c)\,dA$. In this expression the factor $\int z^2\,dA$ is the polar moment of inertia of the section with respect to the axis. Denoting this by J, the resisting moment may be written $\tau J/c$.

THE POLAR MOMENT OF INERTIA of a surface about an axis through its center of gravity and perpendicular to the surface is the sum of the products obtained by multiplying each elementary area by the square of its distance from the center of gravity of its surface, it is equal to the sum of the moments of inertia taken with respect to two axes in the plane of the surface at right angles to each other passing through the center of gravity. It is represented by J, inches^4. For the cross section of a round shaft,

$$J = {}^1/_{32}\,\pi d^4 \quad \text{or} \quad {}^1/_2\,\pi r^4 \qquad (35)$$

for a hollow shaft,

$$J = {}^1/_{32}\,\pi(d^4 - d_1{}^4) \qquad (36)$$

where d is the outside and d_1 the inside diameter, inches, or

$$J = {}^1/_2\,\pi(r^4 - r_1{}^4) \qquad (37)$$

where r is the outside and r_1 the inside radius, inches.

THE POLAR RADIUS OF GYRATION, k_p, sometimes is used in formulas; it is defined as the radius of a circumference along which the entire area of a surface might be concentrated and have the same polar moment of inertia as the distributed area. For a solid circular section,

$$k_p{}^2 = {}^1/_8\,d^2 \qquad (38)$$

for a hollow circular section,

$$k_p{}^2 = {}^1/_8\,(d^2 - d_1{}^2) \qquad (39)$$

12. DETERMINATION OF TORSIONAL STRESSES IN SHAFTS

TORSION FORMULA FOR ROUND SHAFTS. The conditions of equilibrium require that the twisting moment, T, be opposed by an equal resisting moment, T_r, so that for the values of the maximum unit shearing stress, τ, within the proportional limit, the torsion formula for round shafts becomes

$$T_r = T = \tau\frac{J}{c} \qquad (40)$$

If τ is in pounds per square inch, then T_r and T must be in pound-inches, J is in inches^4, and c is in inches. For solid round shafts having a diameter, d, inches,

$$J = {}^1/_{32}\,\pi d^4 \quad \text{and} \quad c = {}^1/_2\,d \qquad (41)$$

and

$$T = {}^1/_{16}\,\pi d^3\tau \quad \text{or} \quad \tau = \frac{16T}{\pi d^3} \qquad (42)$$

For hollow round shafts,

$$J = \frac{\pi(d^4 - d_1{}^4)}{32} \quad \text{and} \quad c = {}^1/_2\,d \qquad (43)$$

and the formula becomes

$$T = \frac{\tau\pi(d^4 - d_1{}^4)}{16d} \quad \text{or} \quad \tau = \frac{16Td}{\pi(d^4 - d_1{}^4)} \qquad (44)$$

The torsion formula applies only to solid circular shafts or hollow circular shafts, and then only when the load is applied in a plane perpendicular to the axis of the shaft and when the shearing proportional limit of the material is not exceeded.

SHEARING STRESS IN TERMS OF HORSEPOWER. If the shaft is to be used for the transmission of power, the value of T, pound-inches, in the above formulas becomes $63{,}030H/N$, where H = horsepower to be transmitted; N = revolutions per minute. The maximum unit shearing stress, pounds per square inch, then is:

$$\text{For solid round shafts:} \quad \tau = \frac{321{,}000H}{Nd^3} \qquad (45)$$

$$\text{For hollow round shafts:} \quad \tau = \frac{321{,}000Hd}{N(d^4 - d_1{}^4)} \qquad (46)$$

If τ is taken as the allowable unit shearing stress, the diameter, d, inches, necessary to transmit a given horsepower at a given shaft speed can then be determined. These formulas give the stress due to torsion only, and allowance must be made for any other loads, as the weight of shaft and pulleys, and tension in belts.

Table 8. Formulas for Torsional Deformation and Stress

General formulas: $\theta = \frac{TL}{KG}$, $\tau = \frac{T}{Q}$, where θ = angle of twist, radians; T = twisting moment, in.-lb; L = length, in.; τ = unit shear stress, psi; G = modulus of rigidity, psi; K, in.^{4}; and Q, in.^{3} are functions of the cross section.

Shape	Formula for K in $\theta = \frac{TL}{KG}$	Formula for Shear Stress
	$K = \frac{\pi d^4}{32}$	$\tau = \frac{16T}{\pi d^3}$
	$K = 1/32\,\pi(d_1^4 - d^4)$	$\tau = \frac{16Td}{\pi(d_1^4 - d^4)}$
	$K = 2/3\,\pi r t^3$	$\tau = \frac{3T}{2\pi r t^2}$
	$K = \frac{\pi a^3 b^3}{a^2 + b^2}$	$\tau = \frac{2T}{\pi a b^2}$
	$K = \frac{\pi a_1^3 b_1^3}{a_1^2 + b_1^2}[(1+q)^4 - 1]$ $q = \frac{a - a_1}{a_1}$ $q = \frac{b - b_1}{b_1}$	$\tau = \frac{2T}{\pi a_1 b_1^2[(1+q)^4 - 1]}$
	$K = \frac{b^4\sqrt{3}}{80}$	$\tau = \frac{20T}{b^3}$
	$K = 2.69b^4$	$\tau = \frac{1.09T}{b^3}$
	$K = \frac{ab^3}{16}\left[\frac{16}{3} - 3.36\frac{b}{a}\left(1 - \frac{b^4}{12a^4}\right)\right]$	$\tau = \frac{(3a + 1.8b)T}{a^2 b^2}$
	$K = \frac{2t_1 t_2(a - t_2)^2(b - t_1)^2}{a t_2 + b t_1 - t_2^2 - t_1^2}$	$\tau = \frac{T}{2t_2(a - t_2)(b - t_1)}$
	$K = 0.1406b^4$	$\tau = \frac{4.8T}{b^3}$

(*Table continued on p. 8-30*)

Table 8. Formulas for Torsional Deformation and Stress—*Continued*

General formulas. $\theta = \frac{TL}{KG}$, $\tau = \frac{T}{Q}$, where θ = angle of twist, radians; T = twisting moment, in.-lb; L = length, in.; τ = unit shear stress, psi; G = modulus of rigidity, psi; K, in.^{4}; and Q, in.^{3} are functions of the cross section.

Shape	Formula for K in $\theta = \frac{TL}{KG}$	Formula for Shear Stress
	r = fillet radius D = diameter largest inscribed circle $K = 2K_1 + K_2 + 2\alpha D^4$ $K_1 = ab^3\left[\frac{1}{3} - 0.21\frac{b}{a}\left(1 - \frac{b^4}{12a^4}\right)\right]$ $K_2 = cd^3\left[\frac{1}{3} - 0.105\frac{d}{c}\left(1 - \frac{d^4}{192c^4}\right)\right]$ $\alpha = \frac{b}{d}\left(0.07 + 0.076\frac{r}{b}\right)$	For all solid sections of irregular form the maximum shear stress occurs at or very near one of the points where the largest inscribed circle touches the boundary, and of these, at the one where the curvature of the boundary is algebraically least. (Convexity represents positive, concavity negative, curvature of the boundary.) At a point where the curvature is positive (boundary of section straight or convex) this maximum stress is given approximately by: $\tau = G\frac{\theta}{L}c$ or $\tau = \frac{T}{K}c$ where $c = \frac{D}{1 + \frac{\pi^2 D^4}{16A^2}} \times \left[1 + 0.15\left(\frac{\pi^2 D^4}{16A^2} - \frac{D}{2r}\right)\right]$ where D = diameter of largest inscribed circle, r = radius of curvature of boundary at the point (positive for this case), A = area of the section.
	$K = 2K_1 + K_2 + 2\alpha D^4$ $K_1 = ab^3\left[\frac{1}{3} - 0.21\frac{b}{a}\left(1 - \frac{b^4}{12a^4}\right)\right]$ $K_2 = \frac{1}{3}cd^3$ $\alpha = \frac{t}{t_1}\left(0.15 + 0.1\frac{r}{b}\right)$ $t = b$ if $b < d$ $t = d$ if $d < b$ $t_1 = b$ if $b > d$ $t_1 = d$ if $d > b$	
	$K = K_1 + K_2 + \alpha D^4$ $K_1 = ab^3\left[\frac{1}{3} - 0.21\frac{b}{a}\left(1 - \frac{b^4}{12a^4}\right)\right]$ $K_2 = cd^3\left[\frac{1}{3} - 0.105\frac{d}{c}\left(1 - \frac{d^4}{192c^4}\right)\right]$ $\alpha = \frac{b}{d}\left(0.07 + 0.076\frac{r}{b}\right)$	

ANGLE OF TWIST. When the unit shearing stress τ does not exceed the proportional limit, the angle *bod* (Fig. 21) for a solid round shaft may be computed from the formula

$$\theta = \frac{Tl}{GJ} \tag{47}$$

where θ = angle in radians; l = length of shaft in inches; G = shearing modulus of elasticity of the material; T = twisting moment, pound-inches. Values of G for different materials are steel, 12,000,000; wrought iron, 10,000,000; and cast iron, 6,000,000.

When the angle of twist on a section begins to increase in a greater ratio than the twisting moment, it may be assumed that the shearing stress on the outside of the section has reached the proportional limit. The shearing stress at this point may be determined by substituting the twisting moment at this instant in the torsion formula.

TORSION OF NONCIRCULAR CROSS SECTIONS. The analysis of shearing stress distribution along noncircular cross sections of bars under torsion is complex. By drawing two lines at right angles through the center of gravity of a section before twisting, and observing the angular distortion after twisting, it has been found from many experiments that in noncircular sections the shearing unit stresses are not proportional to their distances from the axis. Thus in a rectangular bar there is no shearing stress at the corners of the sections, and the stress at the middle of the wide side is greater than at the middle of the narrow side. In an elliptical bar the shearing stress is greater along the flat side than at the round side.

It has been found by tests (Refs. 6 and 7) as well as by mathematical analysis that the torsional resistance of a section, made up of a number of rectangular parts, is approximately equal to the sum of the resistances of the separate parts. It is on this basis that nearly all the formulas for noncircular sections have been developed. For example, the torsional resistance of an I-beam is approximately equal to the sum of the torsional resistances of the web and the outstanding flanges. In an I-beam in torsion the maximum shearing stress will occur at the middle of the side of the web, except where the flanges are thicker than the web, and then the maximum stress will be at the midpoint of the width of the flange. Re-entrant angles, as those in I-beams and channels, are always a source of weakness in members subjected to torsion. Table 8 gives values of the maximum unit shearing stress τ and the angle of twist θ induced by twisting bars of various cross sections, it being assumed that τ is not greater than the proportional limit.

ULTIMATE STRENGTH IN TORSION. In a torsion failure, the outer fibers of a section are the first to shear, and the rupture extends toward the axis as the twisting is continued. The torsion formula for round shafts has no theoretical basis after the shearing stresses on the outer fibers exceed the proportional limit, as the stresses along the section then are no longer proportional to their distances from the axis. It is convenient, however, to compare the torsional strength of various materials by using the formula to compute values of τ at which rupture takes place. These computed values of the maximum stress sustained before rupture are somewhat higher for iron and steel than the ultimate strength of the materials in direct shear. Computed values of the ultimate strength in torsion are found by experiment to be: cast iron, 30,000 psi; wrought iron, 55,000 psi; medium steel, 65,000 psi; timber, 2000 psi. These computed values of twisting strength may be used in the torsion formula to determine the probable twisting moment that will cause rupture of a given round bar or to determine the size of a bar that will be ruptured by a given twisting moment. In design, large factors of safety should be taken, especially when the stress is reversed as in reversing engines and when the torsional stress is combined with other stresses as in shafting.

13. CYLINDERS AND PLATES

THIN CYLINDERS UNDER INTERNAL PRESSURE. A cylinder is regarded as thin when the thickness of the wall is small compared with the diameter. It is assumed that in such cases the tensile stress across the longitudinal section is uniformly distributed over the thickness of the wall. If P = internal pressure, l = length of cylinder, t = thickness of wall, d = diameter of cylinder, and σ = circumferential tensile stress,

$$Pdl = 2\sigma tl \quad \text{or} \quad \sigma = \frac{Pd}{2t} \tag{48}$$

For resistance to rupture in a circumferential seam, due to pressure on the ends of the cylinder, i.e., the tensile stress across a transverse section,

$$P\frac{\pi d^2}{4} = \sigma t\pi d \quad \text{or} \quad \sigma = \frac{Pd}{4t} \tag{49}$$

If the two equations are compared, it is seen that the resistance to rupture by circumferential stress (eq. 48) is one-half the resistance to rupture by longitudinal stress (eq. 49). For this reason cylindrical boilers are single riveted in the circumferential seams and double or triple riveted in the longitudinal seams.

In using the foregoing formulas to design cylindrical shells or piping, thickness t must be increased to compensate for rivet holes in the joints. Water pipes, particularly those of cast iron, require a high factor of safety, which results in increased thickness to provide security against shocks caused by water hammer or rough handling before they are laid.

Equation 49 applies also to the stresses in the walls of a thin hollow sphere, hemisphere, or dome. When holes are cut, the tensile stresses must be found by the method used in riveted joints. See Section 10, Article 7.

THIN CYLINDERS UNDER EXTERNAL PRESSURE. Equations 48 and 49 apply equally well to cases of external pressure if P is given a negative sign, but the stresses so found are significant only if the pressure and dimensions are such that no buckling can occur.

THICK CYLINDERS. When the thickness of the shell or wall is relatively large, as in guns, hydraulic machinery piping, and similar installations, the variation in stress from the inner surface to the outer surface is relatively large, and the ordinary formulas for

(Continued on p. 8-35)

Table 9. Formulas for Flat Plates

(By permission from *Formulas for Stress and Strain*, 2nd Ed., by R. J. Roark, copyrighted, 1943. McGraw-Hill Book Co., Inc.)

Notation. W = total applied load, lb; w = unit applied load, psi; t = thickness of plate, in.; σ = stress at surface of plate, psi; y = vertical deflection of plate from original position, in.; E = modulus of elasticity; m = reciprocal of ν, Poisson's ratio. q denotes any given point on the surface of plate; r denotes the distance of q from the center of a circular plate. Other dimensions and corresponding symbols are indicated on figures. Positive sign for σ indicates tension at upper surface and equal compression at lower surface; negative sign indicates reverse condition. Positive sign for y indicates upward deflection, negative sign downward deflection. Subscripts r, t, a, and b used with σ denote, respectively, radial direction, tangential direction, direction of dimension a, and direction of dimension b. All dimensions are in inches. All logarithms are to the base e ($\log_e x = 2.3026 \log_{10} x$).

Type of Load and Support	Formulas for Stress and Deflection
Outer edges supported. Uniform load over entire surface.  	Circular Flat Plates  At center: $\max \sigma_r = \sigma_t = \frac{-3W}{8\pi mt^2}(3m+1) \qquad \max y = -\frac{3W(m-1)(5m+1)a^2}{16\pi Em^2t^3}$ At q $\sigma_r = -\frac{3W}{8\pi mt^2}\left[(3m+1)\left(1-\frac{r^2}{a^2}\right)\right] \qquad \sigma_t = -\frac{3W}{8\pi mt^2}\left[(3m+1)-(m+3)\frac{r^2}{a^2}\right]$ $y = -\frac{3W(m^2-1)}{8\pi Em^2t^3}\left[\frac{(5m+1)a^2}{2(m+1)}+\frac{r^4}{2a^2}-\frac{(3m+1)r^2}{m+1}\right]$
Outer edges fixed. Uniform load over entire surface.  	At center: $\sigma_r = \sigma_t = -\frac{3W(m+1)}{8\pi mt^2} \qquad \max y = -\frac{3W(m^2-1)a^2}{16\pi Em^2t^3}$ At q: $\sigma_r = \frac{3W}{8\pi mt^2}\left[(3m+1)\frac{r^2}{a^2}-(m+1)\right] \qquad \sigma_t = \frac{3W}{8\pi mt^2}\left[(m+3)\frac{r^2}{a^2}-(m+1)\right]$ $y = \frac{-3W(m^2-1)}{16\pi Em^2t^3}\left[\frac{(a^2-r^2)^2}{a^2}\right]$
Outer edges supported. Uniform load over concentric circular area of radius r_0.  	At q, $r < r_0$: $\sigma_r = -\frac{3W}{2\pi mt^2}\left[m+(m+1)\log\frac{a}{r_0}-(m-1)\frac{r_0^2}{4a^2}-(3m+1)\frac{r^2}{4r_0^2}\right]$ $\sigma_t = -\frac{3W}{2\pi mt^2}\left[m+(m+1)\log\frac{a}{r_0}-(m-1)\frac{r_0^2}{4a^2}-(m+3)\frac{r^2}{4r_0^2}\right]$ $y = -\frac{3W(m^2-1)}{16\pi Em^2t^3}\left[4a^2-5r_0^2+\frac{r^4}{r_0^2}-(8r^2+4r_0^2)\log\frac{a}{r_0}-\frac{2(m-1)r_0^2(a^2-r^2)}{(m+1)a^2}+\frac{8m(a^2-r^2)}{m+1}\right]$ At q, $r > r_0$: $\sigma_r = -\frac{3W}{2\pi mt^2}\left[(m+1)\log\frac{a}{r}-(m-1)\frac{r_0^2}{4a^2}+(m-1)\frac{r_0^2}{4r^2}\right]$ $\sigma_t = -\frac{3W}{2\pi mt^2}\left[(m-1)+(m+1)\log\frac{a}{r}-(m-1)\frac{r_0^2}{4a^2}-(m-1)\frac{r_0^2}{4r^2}\right]$ $y = -\frac{3W(m^2-1)}{16\pi Em^2t^3}\left[\frac{(12m+4)(a^2-r^2)}{m+1}-\frac{2(m-1)r_0^2(a^2-r^2)}{(m+1)a^2}-(8r^2+4r_0^2)\log\frac{a}{r}\right]$ At center: $\max \sigma_r = \sigma_t = -\frac{3W}{2\pi mt^2}\left[m+(m+1)\log\frac{a}{r_0}-(m-1)\frac{r_0^2}{4a^2}\right]$ $\max y = -\frac{3W(m^2-1)}{16\pi Em^2t^3}\left[\frac{(12m+4)a^2}{m+1}-4r_0^2\log\frac{a}{r_0}-\frac{(7m+3)r_0^2}{m+1}\right]$

At outer edge: $\max \sigma_r = \frac{3W}{2\pi t^2}\left[1 - \frac{2mb^2 - 2b^2(m+1)\log\frac{a}{b}}{a^2(m-1)+b^2(m+1)}\right] = \max\sigma \text{ when } \frac{a}{b} < 2.4$ At inner edge: $\max \sigma_t = \frac{3W}{2\pi m t^2}\left[1 + \frac{ma^2(m-1) - mb^2(m+1) - 2(m^2-1)a^2\log\frac{a}{b}}{a^2(m-1)+b^2(m+1)}\right]$ $= \max\sigma \text{ when } \frac{a}{b} > 2.4$ $\max y = -\frac{3W(m^2-1)}{4\pi m^2 E t^3} \times$ $\left[a^2 - b^2 + \frac{2mb^2(a^2-b^2) - 8ma^2b^2\log\frac{a}{b} + 4a^2b^2(m+1)\left(\log\frac{a}{b}\right)^2}{a^2(m-1)+b^2(m+1)}\right]$
Outer edge fixed. Uniform moment along inner edge.  	At inner edge: $\max \sigma_r = \frac{6M}{t^2}$ $\max y = \frac{6M(m^2-1)}{mEt^3}\left[\frac{a^2b^2 - b^4 - 2a^2b^2\log\frac{a}{b}}{a^2(m-1)+b^2(m+1)}\right]$ At outer edge: $\sigma_r = -\frac{6M}{t^2}\left[\frac{2mb^2}{(m+1)b^2+(m-1)a^2}\right]$
Outer edge supported. Unequal uniform moments along edges.  	At q: $\sigma_r = \frac{6}{t^2(a^2-b^2)}\left[a^2M_a - b^2M_b - \frac{a^2b^2}{r^2}(M_a - M_b)\right]$ $\sigma_t = \frac{6}{t^2(a^2-b^2)}\left[a^2M_a - b^2M_b + \frac{a^2b^2}{r^2}(M_a - M_b)\right]$ From outer edge level: $y = \frac{12(m^2-1)}{mEt^3(a^2-b^2)}\left[\frac{a^2-r^2}{2}\left(\frac{a^2M_a - b^2M_b}{m+1}\right) + \log\frac{a}{r}\left(\frac{a^2b^2(M_a-M_b)}{m-1}\right)\right]$

thin wall cylinders are no longer applicable. The maximum stresses can be computed from eqs. 50, 51, and 52.

$$\sigma_t = \frac{P_1r_1^2 - P_2r_2^2 + \frac{r_1^2r_2^2}{x^2}(P_1 - P_2)}{r_2^2 - r_1^2} \tag{50}$$

$$\sigma_r = \frac{P_2r_2^2 - P_1r_1^2 + \frac{r_1^2r_2^2}{x^2}(P_1 - P_2)}{r_2^2 - r_1^2} \tag{51}$$

With the maximum shear theory the criterion of failure, the maximum shear stress for the case of internal pressure only ($P_2 = 0$, $x = r_1$) is

$$\tau = P_1\frac{r_2^2}{r_2^2 - r_1^2} \tag{52}$$

where σ_t = tangential stress, σ_r = radial stress, τ = shear stress, P_1 = internal pressure, P_2 = external pressure, r_1 = internal radius, r_2 = external radius, x = radial coordinate of any point in the wall, the minimum and maximum values for x are r_1 and r_2, respectively

Table 10. Areas of Contact and Pressures with Two Surfaces in Contact

In *shrinkage fits* a hollow cylinder or collar is forced over a cylinder having an outer diameter slightly greater than the inside diameter of the outer cylinder. This will cause compressive stresses in the inner cylinder and tensile stresses in the outer cylinder. Timoshenko and Lessells (Ref. 8) give the equation for the pressure p, pounds per square inch, between the cylinders as

$$p = \frac{E\delta}{b} \frac{(b^2 - a^2)(c^2 - b^2)}{2b^2(c^2 - a^2)} \tag{53}$$

where E = modulus of elasticity, a = inner radius of inner cylinder, b = outer radius of inner cylinder, c = outer radius of outer cylinder, δ = amount by which the outer radius of the inner cylinder exceeds the inner radius of the outer cylinder. With the pressures known, external pressure on the inner cylinder and internal pressure on the outer cylinder, the stresses can be computed by means of eqs. 50 and 51.

PLATES. The formulas which apply for plates are based on the assumptions that the plate is flat, of uniform thickness, and of homogeneous isotropic material, thickness is not greater than one-fourth the least transverse dimension, maximum deflection is not more than one-half the thickness, all forces are normal to the plane of the plate, and the plate is nowhere stressed beyond the elastic limit. In Table 9 are formulas for deflection and stress for various shapes, forms of load and edge conditions. For further information see Ref. 9.

14. CONTACT STRESSES

The stresses caused by the pressure between elastic bodies are of importance in connection with the design or investigation of ball and roller bearings, trunnions, expansion rollers, track stresses, gear teeth, etc.

CONTACT STRESS THEORY. H. Hertz (Ref. 10) developed the mathematical theory for the surface stresses and the deformations produced by pressure between curved bodies, and the results of his analysis are supported by research. Formulas based on this theory give the maximum compressive stresses which occur at the center of the surfaces of contact, but do not consider the maximum subsurface shear stresses nor the maximum tensile stresses which occur at the boundary of the contact area. In Table 10 formulas are given for the elastic stress and deformation produced by bodies in contact. Numerous tests have been made to determine the bearing strength of balls and rollers, but there is difficulty in interpreting the results for lack of a satisfactory criterion of failure. One arbitrary criterion of failure is the amount of allowable plastic yielding. For further information on contact stresses see Refs. 9, 11, and 12.

DYNAMIC STRESSES

DYNAMIC STRESSES occur where the dimension of time is necessary in defining the loads. They include creep, fatigue, and impact stresses.

CREEP STRESSES occur when either the load or deformation progressively vary with time. They are usually associated with noncyclic phenomena.

FATIGUE STRESSES occur when the cyclic variation of either load or strain is coincident with respect to time.

IMPACT STRESSES occur from loads which are transient with time. The duration of the load application is of the same order of magnitude as the natural period of vibration of the specimen.

15. WORK AND RESILIENCE

EXTERNAL WORK: Let P = axial load, pounds, on a bar, producing an internal stress not exceeding the elastic limit; σ = unit stress produced by P, pounds per square inch; A = cross-sectional area, square inches; l = length of bar, inches; e = deformation, inches; E = modulus of elasticity; W = external work performed on bar, inch-pounds = $^1/_2\,Pe$. Then

$$W = \frac{1}{2} A\sigma \left(\frac{\sigma l}{E}\right) = \frac{1}{2}\left(\frac{\sigma^2}{E}\right) Al \qquad (1)$$

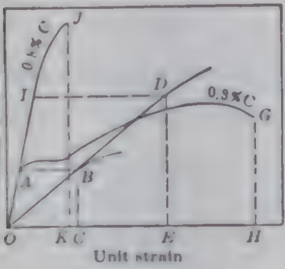

FIG. 1. Work areas on stress-strain diagram.

The factor $(^1/_2)\,(\sigma^2/E)$ is the work required per unit volume, the volume being Al. It is represented on the stress-strain diagram by the area ODE or area OBC (Fig. 1), in which DE and BC are ordinates representing the unit stresses considered.

RESILIENCE is the strain energy which may be recovered from a deformed body when the load causing the stress is removed. Within the proportional limit, the resilience is equal to the external work performed in deforming the bar, and may be determined by eq. 1. When σ is equal to the proportional limit, the factor $(^1/_2)(\sigma^2/E)$ is the *modulus of resilience*, i.e., the measure of capacity of a unit volume of material to store strain energy up to the proportional limit. Average values of the modulus of resilience under tensile stress are given in Table 1.

Table 1. Average Values of Tensile Modulus of Resilience and Toughness

Material	Modulus of Resilience, in.-lb per cu in.	Relative Toughness (Area under Curve of Stress-deformation Diagram)
Gray cast iron	1.2	70
Malleable cast iron	17.4	3,800
Wrought iron	11.6	11,000
Low-carbon steel	15.0	15,700
Medium-carbon steel	34.0	16,300
High-carbon steel	94.0	5,000
Ni-Cr steel, hot-rolled	94.0	44,000
Vanadium steel, 0.98% C, 0.2% V, heat-treated	260.0	22,000
Duralumin, 17 ST	45.0	10,000
Rolled bronze	57.0	15,500
Rolled brass	40.0	10,000
Oak	2.3 *	13 *

* Bending.

The total resilience of a bar is the product of its volume and the modulus of resilience. These formulas for work performed on a bar, and its resilience, do not apply if the unit stress is greater than the proportional limit.

WORK REQUIRED FOR RUPTURE. Since beyond the proportional limit the strains are not proportional to the stresses, $^1/_2\,P$ does not express the mean value of the force acting. Equation 1, therefore, does not express the work required for strain after the proportional limit of the material has been passed, and cannot express the work required for rupture. The work required per unit volume to produce strains beyond the proportional limit or to cause rupture may be determined from the stress-strain diagram as it is measured by the area included between the axis of abscissas, and the stress-strain curve up to the strain in question, as $OAGH$ or OJK (Fig. 1). This area, however, does not represent the resilience, since part of the work done on the bar is present in the form of hysteresis losses and cannot be recovered.

DAMPING CAPACITY (HYSTERESIS). Observations show that when a tensile load is applied to a bar it does not produce the complete elongation immediately, but there is a definite time lapse which depends on the nature of the material and the magnitude of the stresses involved. In parallel with this it is also noted that, upon unloading, complete recovery of energy does not occur. This phenomenon is variously termed *elastic hysteresis* or, for vibratory stresses, damping. Figure 2 shows a typical hysteresis loop obtained for one cycle of loading. The area of this hysteresis loop, representing the energy dissipated per cycle, is a measure of the

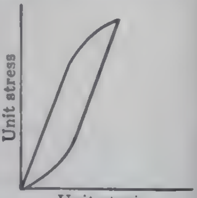

FIG. 2. Hysteresis loop for loading and unloading.

damping properties of the material. While the exact mechanism of damping has not been fully investigated, it has been found that under vibratory conditions the energy dissipated in this manner varies approximately as the cube of the stress.

16. IMPACT STRESSES IN BARS AND BEAMS

EFFECT OF SUDDEN LOADS. If a sudden load P is applied to a bar, it will cause a deformation el, and the work done by the load will be Pel. Since the external work equals the internal work, $Pel = \sigma^2 Al/2E$, and since $e = \sigma/E$, $P = \sigma A/2$, or $\sigma = 2P/A$. The unit stress and also the unit strain are double those obtained by an equal load applied gradually. However, the bar does not maintain equilibrium at the point of maximum stress and strain. After a series of oscillations, however, in which the surplus energy is dissipated in damping, the bar finally comes to rest with the same strain and stress as that due to the equal static load.

STRESS DUE TO LIVE LOADS. In structural design two loads are considered, the dead load or weight of the structure and the live load or superimposed loads to be carried. The stresses due to the dead load and to the live load are computed separately, each being regarded as a static load. It is obvious that the stress due to the live load may be greatly increased, depending on the suddenness with which the load is applied. It has been shown above that the stress due to a suddenly applied load is double the stress caused by a static load. The term *coefficient of impact* is used extensively in structural engineering to denote the number by which the computed static stress is multiplied to obtain the value of the increased stress assumed to be caused by the suddenness of the application of the live load. If σ = static unit stress computed from the live load, and i = coefficient of impact, then the increase of unit stress due to sudden loading is $i\sigma$, and the total unit stress due to live load is $\sigma + i\sigma$. The value of i has been determined by empirical methods and varies according to different conditions.

In the building codes of most cities, specified floor loadings for buildings include the impact allowance, and no increase is needed for live loads except for special cases of vibration or other unusual conditions. For railroad bridges, the value of i depends upon the proportion of the length of the bridge which is loaded. No increase in the static stress is needed when the mass of the structure, as in monolithic concrete, is great. For machinery and for unusual conditions, such as elevator machinery and its supports, each structure should be considered by itself and the coefficient assumed accordingly. It should be noted that the meaning of the word impact used above differs somewhat from its strict theoretical meaning and as it is used in the next paragraph. The use of the terms impact and coefficient of impact in connection with live load stresses is, however, very general.

AXIAL IMPACT ON BARS. A load P dropped from a height h onto the end of a vertical bar of cross-sectional area A, rigidly secured at the bottom end, produces in the bar a unit stress which increases from 0 up to σ', with a corresponding total strain increasing from 0 up to e_1. The work done on the bar is $P(h + e_1)$, which, provided no energy is expended in hysteresis losses or in giving velocity to the bar, is equal to the energy $^1/_2\,\sigma' Ae_1$ stored in the bar; that is,

$$P(h + e_1) = {}^1/_2\,\sigma' Ae_1 \tag{2}$$

If e = strain produced by a static load P, within the proportional limit

$$\frac{e}{e_1} = \frac{P/A}{\sigma'} \tag{3}$$

Combining this with eq. 2 gives

$$\sigma' = \sigma + \sigma\sqrt{1 + 2\frac{h}{e}} \tag{4}$$

$$e_1 = e + e\sqrt{1 + 2\frac{h}{e}} \tag{5}$$

A wrought-iron bar 1 in. square and 5 ft long under a static load of 5000 lb will be shortened about 0.012 in., assuming no lateral flexure to occur; but, if a weight of 5000 lb drops on its end from a height of 0.048 in., a stress of 20,000 lb will be produced.

Equations 4 and 5 give values of stress and strain that are somewhat high because part of the energy of the applied force is not effective in producing stress, but is expended in overcoming the inertia of the bar and in producing local stresses. For light bars they give approximately correct results.

If the bar is horizontal and is struck at one end by a weight P, moving with a velocity V, the strain produced is e_1. Then, as before, $^1/_2\,\sigma' Ae_1 = Ph$. In this case $h = V^2/2g =$

height from which P would have to fall to acquire velocity V (g = acceleration due to gravity = 32.16 ft per sec^2). Combining with eq. 3,

$$\sigma' = \sigma \sqrt{2\frac{h}{e}} \tag{6}$$

$$e_1 = e\sqrt{2\frac{h}{e}} \tag{7}$$

IMPACT ON BEAMS. If a weight P falls on a horizontal beam from a height h, producing a maximum deflection y and a maximum unit stress σ' in the extreme fiber, the values of σ' and y are given by

$$\sigma' = \sigma + \sigma\sqrt{1 + 2\frac{h}{y}} \tag{8}$$

$$y_1 = y + y\sqrt{1 + 2\frac{h}{y}} \tag{9}$$

where σ = extreme fiber unit stress and y = deflection due to P, considered as a static load. The value of σ may be obtained from the flexure formula (p. 8-08); that of y from the proper formula for deflection under static load.

If a weight P moving horizontally with a velocity V strikes a beam (the ends of which are secured against horizontal movement), the maximum fiber unit stress and the maximum lateral deflection are given by

$$\sigma' = \sigma\sqrt{2\frac{h}{y}} \tag{10}$$

$$y_1 = y\sqrt{2\frac{h}{y}} \tag{11}$$

where σ and y are as before and h is height through which P would have to fall to acquire the velocity V. These formulas, like those for axial impact on bars, give results higher than those observed in tests, particularly if the weight of the beam is great. For further discussion, see Ref. 1, Chapter XI.

RUPTURE FROM IMPACT. Rupture may be caused by impact provided the load has the requisite velocity. The above formulas, however, do not apply since they are valid only for stresses within the proportional limit. It has been found that the dynamic properties of a material are dependent on volume, velocity of the applied load, and material condition. If the velocity of the applied load is kept within certain limiting values, the total energy values for static and dynamic conditions are identical. If the velocity is increased, the impact values are considerably reduced. For further information see Ref. 2.

17. STEADY VIBRATORY STRESSES IN BARS AND BEAMS

For steady vibratory stresses the deflection of the bar, or beam, will be increased by the dynamic magnification factor (see Section 9 of this volume). The relation is given by

$$\delta_{\text{dynamic}} = \delta_{\text{static}} \times \text{dynamic magnification factor}$$

An example of the calculating procedure for the case of no damping losses is

$$\delta_{\text{dynamic}} = \delta_{\text{static}} \times \frac{1}{1 - \left(\frac{\omega}{\omega_n}\right)^2} \tag{12}$$

where ω is the frequency of oscillation of the load and ω_n the natural frequency of oscillation of the bar. ω_n is determined by

$$\omega_n = \sqrt{\frac{3EIg}{L^3W}} \tag{13}$$

where E = modulus of elasticity, I = moment of inertia, g = acceleration of gravity, L = length of bar, and W = weight of oscillating load.

18. FATIGUE

PARTS SUBJECTED TO REPEATED STRESS. Where parts of a structure or machine are subjected to varying or repeated loads, the ordinary methods of computing stresses and of determining the strength of materials under static load conditions are not satisfactory. In general, more than one-half to ten million repetitions of loading are necessary before the parts come under this classification. Such parts are crankshafts, shafts carrying rotating members (as in motors and generators), turbine blades, valve parts, piston rods, floor beams in elevated railroads, etc.

NATURE OF FAILURE. The failure of a ductile member caused by repeated loads is not accompanied by noticeable yielding; the failure is a gradual or progressive fracture. The fracture seems to start at some point in the member at which the stress is much larger than the calculated stress. This high localized stress seems to cause, or at least is accompanied by, a small crack which gradually spreads as the stress is repeated until the whole member ruptures without measurable yielding. The fatigue failure of a ductile material is similar to that of a static failure of a brittle material.

DETERMINATION OF ENDURANCE LIMIT. The highest unit stress σ at which a material can be subjected to a very large number of repetitions of load N without evidence of failure is the *endurance limit* of the material. It is usually found for any given material by constructing a σ-N curve for that particular metal from data obtained by tests. A piece of metal is loaded so as to produce a given stress, the load being repeated until failure occurs. Other specimens are then tested at different values of the unit stress until enough points have been obtained to plot a curve. This curve will incline steeply at the higher stresses and gradually flatten out at the lower stresses until, for steel, it approaches asymptotically a limiting stress called the endurance limit. For alloys and materials subjected to corrosive conditions, the σ-N curve continues to slope gradually down; the endurance limit is usually set at that stress which corresponds to approximately 10×10^6 cycles. The most common test is reversed bending by the rotating beam method since this specimen is most easily made and the testing machines are the least costly. Tests are also made in direct tension, direct shear, direct compression, reversed torsion, and in various combinations of them. Typical σ-N curves are shown in Fig. 3.

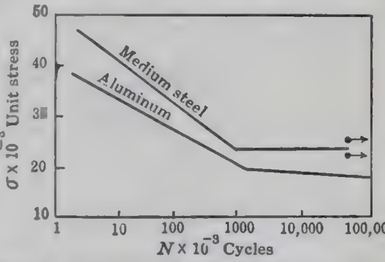

FIG. 3. Typical σ-N curves of fatigue resistance.

EFFECT OF SCRATCHES AND DEFECTS ON ENDURANCE LIMIT OF ROLLED OR FORGED FERROUS METALS. The beginning of rupture under repeated stress usually occurs at a point of discontinuity in the material. The same principle applies to a discontinuity on the outer surface where, in bending or torsion, the stress is greatest. The presence of scratches, sharp corners, or grooves reduces the endurance limit an appreciable amount. Moore and Kommers (Ref. 3) obtained the data given in Table 2. The tests were made on bars 0.40 in. in diameter. Horger and Niefert (Ref. 4) have made similar tests which corroborate the earlier work. It has also been found that the effect of scratches, grooves, etc., is not so pronounced in cast iron as in steel.

Table 2. Fatigue Endurance Limits

Data from *Bulletin* 124, University of Illinois Engineering Experiment Station.

0.49% C Quenched and Drawn 197 Brinell Steel

Finish	Endurance Limit, psi
High polish, longitudinal	51,000
00 Emery	48,000
Ground	45,000
Smooth turned	43,000
Rough turned	42,000

For keyways on shafts, Thum (Ref. 5) has determined that, for a soft steel of tensile strength 60,000 psi, an end-milled keyway reduced the strength to 20,500 psi, whereas a face-milled keyway reduced the strength to 28,000 psi.

Sharp corners (Ref. 6), oil holes (Ref. 7), press fits and surface rolling (Ref. 8), all produce marked reductions in the strength of the material. See also Article 7, Section 1 of this volume.

EFFECT OF RANGE OF STRESS. The endurance limit as determined by a rotating beam is the endurance limit for a complete reversal of stress from tension to compression and vice-versa. The endurance limit is less for a complete reversal than it is for those stress combinations where the stress goes only from a maximum to zero, or from a maximum to a minimum which is above zero. This is discussed further in Article 25 of this Section.

EFFECT OF CORROSION. The endurance limit of steels which have been treated (pickling) prior to use in an application of repeated stress with no further corrosion during stressing is affected considerably by roughening of the surface (i.e., production of pits and notches on the surface of the material). It is even more serious to have corrosion occur simultaneously with repeated stress. One explanation advanced is that a pit or notch formed by corrosion is opened up when tension is applied to the piece and it becomes filled with rust or other products of corrosion. When the tension is released and the pit closes down on the corrosion products it contains, these products exert a wedge action to produce cracking. The crack increases the local stress, and matters get progressively worse. Also, repeated stress tends to crack any protective coating of a film of corrosion products and thus allows continued corrosion at the cracks. This phenomenon is clearly outlined in the work of McAdam and Geil (Ref. 9).

Under corrosive conditions, steels have no endurance limit; the σ-N curve never becomes horizontal but continues to drop. Thus no corrodible steel can last indefinitely under corrosive conditions and repeated stress, no matter how small that stress is. (See also Ref. 10.)

The most effective method of protection is to keep the parts subjected to repeated loads from contact with corrosive agents. Where this is not possible, a protective coating of some elastic material such as varnish, cement, or enamel will aid. (See also Section 3.)

EFFECT OF SIZE. Tests made on specimens 0.3 in. in diameter and larger indicate a reduction of fatigue strength of approximately 10% for an increase in size from 0.3 to 1.0 in. in diameter. In specimens above 1 in. in diameter there was little variation in fatigue strength in geometrically similar specimens without stress concentration. However, with geometrically similar specimens having holes, fillets, and artificial cracks, the smaller specimens gave higher endurance limits than the larger ones (i.e., the strength-reduction factor is lower for the small specimens).

EFFECT OF SPEED. There seems to be little change in the fatigue strength for speeds up to 3000 rpm. However, from 3000 to 120,000 rpm, tests have indicated an increase of about 15% in the endurance limit and some increase in life.

EFFECT OF COLD WORKING. Cold drawing and cold working, as with static strength, increase the fatigue strength. The usefulness of this process is limited because of its tendency to introduce internal strains and minute cracks. Tests have indicated also that by understressing a specimen, that is, subjecting it to a certain safe range of stress before subjecting it to a higher range of stress, a permanent increase of as much as 30% has been obtained in the fatigue strength.

EFFECT OF TEMPERATURE. As the material is subjected to temperature above room temperature under repeated stress conditions, the fatigue strength drops. In one set of data reported the endurance limit dropped 10, 37, and 70% for temperature of 300, 400, and 500 F, respectively.

19. CREEP

INTRODUCTION. Materials subjected to a constant stress at elevated temperatures deform continuously with time, and the behavior under these conditions is different from the behavior at normal temperatures. This continuous deformation with time is called creep. In some applications the permissible creep deformations are critical; in others of no significance. But the existence of creep necessitates information on the creep deformations that may occur during the expected life of the machine.

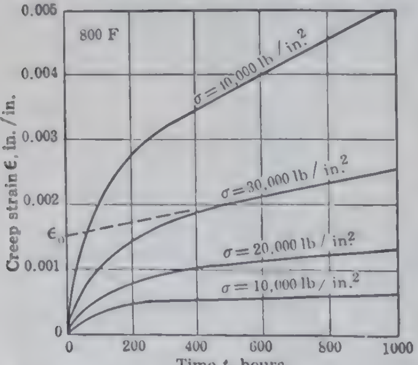

FIG. 4. Curves of creep strain for various stress levels.

MECHANISM OF CREEP FAILURE. There are generally four distinct phases distinguishable during the course of creep failure. The elapsed time per stage depends on the material, temperature, and stress condition. They are: (*a*) Initial phase—where the total deformation is partially elastic and partially plastic. (*b*) Second phase—where the creep rate decreases with time, indicating the effect of strain hardening. (*c*) Third phase—where the effect of strain hardening is counteracted by the annealing influence of the high temperature which produces a constant or minimum creep rate. (*d*) Final phase—where the creep rate increases until fracture occurs due to the decrease in cross-sectional area of the specimen.

CREEP EQUATIONS. In conducting a conventional creep test, curves of strain as a function of time are obtained for groups of specimens; each specimen in one group being subjected to a different constant stress, while all of the specimens in the group are tested at one temperature.

In this manner families of curves like those shown in Fig. 4 are obtained. Several methods have been proposed for the interpretation of such data. (See Ref. 11.) Two frequently used expressions of the creep properties of a material can be derived from the data in the following form:

$$C = B\sigma^m$$
$$\epsilon = \epsilon_0 + Ct \tag{14}$$

where C = creep rate, B, m = experimental constants, σ = stress, ϵ = creep strain at any time t, ϵ_0 = zero time strain intercept, and t = time. See Fig. 5.

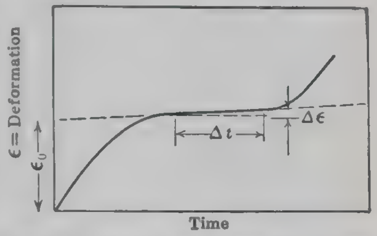

Fig. 5. Method of determining creep rate.

STRESS RELAXATION. Various types of bolted joints and shrink or press fit assemblies are applications of creep taking place with diminishing stress. This deformation tends to loosen the joint and produce a stress reduction or stress relaxation. The performance of a material to be used under diminishing creep-stress condition is determined by a tensile stress-relaxation test.

WORKING STRESSES

20. COMBINED STRESS

Under certain circumstances of loading a body is subjected to a combination of tensile, compressive, and or shear stresses. For example, a shaft which is simultaneously bent and twisted is subjected to combined stresses, namely, longitudinal tension and compression and torsional shear. For the purposes of analysis it is convenient to reduce such systems of combined stresses to a basic system of stress coordinates known as principal stresses. These stresses act on axes which differ in general from the axes along which the applied stresses are acting and represent the maximum and minimum values of the normal stresses for the particular point considered.

DETERMINATION OF PRINCIPAL STRESSES. The expressions for the principal stresses in terms of the stresses along the x and y axes are

$$\sigma_1 = \frac{\sigma_x + \sigma_y}{2} + \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{1}$$

$$\sigma_2 = \frac{\sigma_x + \sigma_y}{2} - \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{2}$$

$$\tau_1 = \pm\sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{3}$$

where σ_1, σ_2, and τ_1 are the principal stress components and σ_x, σ_y, and τ_{xy} the calculated stress components, all of which are determined at any particular point (Fig. 1).

GRAPHICAL METHOD OF PRINCIPAL STRESS DETERMINATION—MOHR'S CIRCLE. Let the axes x and y be chosen to represent the directions of the applied normal and shearing stresses, respectively (Fig. 2). Lay off to suitable scale distances $OA = \sigma_x$, $OB = \sigma_y$, and $BC = AD = \tau_{xy}$. With point E as a center construct the circle DFC. Then OF and OG are the principal stresses σ_1 and σ_2 respectively, and EC the maximum shear stress τ_1. The inverse also holds—that is, given the principal stresses, σ_x and σ_y can be determined on any plane passing through the point.

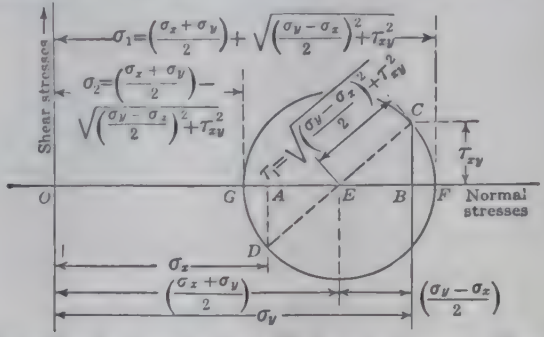
STRESS-STRAIN RELATIONS. The linear relation between components of stress and strain is known as *Hooke's law.* This relation for the two-dimensional case can be expressed as

$$e_x = \frac{1}{E}(\sigma_x - \nu\sigma_y) \tag{4}$$

$$e_y = \frac{1}{E}(\sigma_y - \nu\sigma_x) \tag{5}$$

$$\gamma_{xy} = \frac{1}{G}\tau_{xy} \tag{6}$$

where σ_x, σ_y, and τ_{xy} are the stress components of a particular point, ν = Poisson's ratio, E = modulus of elasticity, G = modulus of rigidity, and e_x, e_y, and γ_{xy} = strain components.



Shear stresses
$\sigma_1=\left(\frac{\sigma_x+\sigma_y}{2}\right)+\sqrt{\left(\frac{\sigma_y-\sigma_x}{2}\right)^2+\tau_{xy}^2}$

21. STRENGTH THEORIES

The determination of the magnitudes and directions of the principal stresses and strains and of the maximum shearing stresses is carried out for the purpose of establishing criteria of failure within the material under the anticipated loading conditions. To this end several theories have been advanced to elucidate these criteria. The more noteworthy ones are listed below. The theories are based on the assumption that the principal stresses do not change with time, an assumption that is justified since the applied loads in most cases are synchronous.

MAXIMUM-STRESS THEORY (RANKINE'S THEORY). This theory is based on the assumption that failure will occur when the maximum value of the greatest principal stress reaches the value of the maximum stress σ_{max} at failure in the case of simple axial loading. Failure is then defined as

$$\sigma_1 \text{ or } \sigma_2 = \sigma_{max} \tag{7}$$

MAXIMUM-STRAIN THEORY (SAINT VENANT). This theory is based on the assumption that failure will occur when the maximum value of the greatest principal strain reaches the value of the maximum strain e_{max} at failure in the case of simple axial loading. Failure is then defined as

$$e_1 \text{ or } e_2 = e_{max} \tag{8}$$

If $e_{\max}$ does not exceed the linear range of the material eq. 8 may be written as

$$\sigma_1 - \nu\sigma_2 = \sigma_{\max} \tag{9}$$

MAXIMUM-SHEAR THEORY (GUEST). This theory is based on the assumption that failure will occur when the maximum shear stress reaches the value of the maximum shear stress at failure in simple tension. Failure is then defined as

$$\tau_1 = \tau_{\max} \tag{10}$$

DISTORTION-ENERGY THEORY (HENCKY-VON MISES) (SHEAR ENERGY). This theory is based on the assumption that failure will occur when the distortion energy corresponding to the maximum values of the stress components equals the distortion energy at failure for the maximum axial stress. Failure is then defined as

$$\sigma_1^2 - \sigma_1\sigma_2 + \sigma_2^2 = \sigma_{\max}^2 \tag{11}$$

STRAIN-ENERGY THEORY. This theory is based on the assumption that failure will occur when the total strain energy of deformation per unit volume in the case of combined stress is equal to the strain energy per unit volume at failure in simple tension. Failure is then defined as

$$\sigma_1^2 - 2\nu\sigma_1\sigma_2 + \sigma_2^2 = \sigma_{\max}^2 \tag{12}$$

COMPARISON OF THEORIES. Figure 3 compares the five foregoing theories. In general the distortion-energy theory is the most satisfactory for ductile materials and the maximum-stress theory for brittle materials. The maximum-shear theory gives conservative results for both ductile and brittle materials. The conditions for yielding, according to the various theories, are given in Table 1, taking $\nu = 0.300$ as for steel.

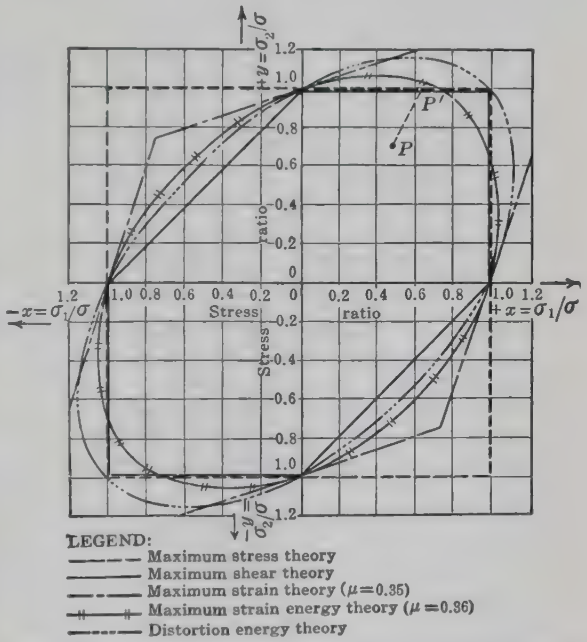

FIG. 3. Comparison of five theories of failure. (Reproduced by permission from Joseph Marin, *op. cit.*)

Table 1. Comparison of Stress Theories

$\tau = \sigma_{yp}$ (from the maximum-stress theory)

$\tau = 0.77\sigma_{yp}$ (from the maximum-strain theory)

$\tau = 0.50\sigma_{yp}$ (from the maximum-shear theory)

$\tau = 0.62\sigma_{yp}$ (from the maximum-strain-energy theory)

22. STRESS CONCENTRATIONS

The direct design procedure described above assumes no abrupt changes in cross section, discontinuities in the surface or holes, etc., through the member. In most structural parts this is not the case. The stresses produced at these discontinuities are different in magnitude from those calculated by the foregoing methods. The effect of the localized increase in stress, such as that caused by a notch, fillet, hole, or similar *stress raiser*, depends mainly on the type of loading, the geometry of the part, and the material. As a result, it is necessary to consider a stress-concentration factor K_t which is defined by the relationship

$$K_t = \frac{\sigma_{\max}}{\sigma_{\text{nominal}}} \tag{13}$$

In general $\sigma_{\max}$ will have to be determined by the methods of experimental stress analysis or the theory of elasticity, and σ_{nominal} by a simple theory such as $\sigma = P/A$, $\sigma = Mc/I$, $\tau = Tc/J$ without taking into account the variations in stress conditions caused by geometrical discontinuities such as holes, grooves, and fillets. For ductile materials it is not customary to apply stress concentration factors to members under static loading. For brittle materials, however, stress concentration is serious and should be considered.

STRESS CONCENTRATION FACTORS FOR FILLETS, KEYWAYS, HOLES, AND SHAFTS. In Table 2 selected stress-concentration factors have been given from a complete table in Ref. 1.

Table 2. Stress-concentration Factors

	3.5		1.76	1.54	1.40	1.23	1.10

23. STATIC WORKING STRESSES

DUCTILE MATERIALS. For ductile materials the criteria for working stresses are

$$\sigma_w = \frac{\sigma_{yp}}{n} \qquad \text{(tension and compression)} \tag{14}$$

$$\tau_w = \frac{1}{2}\frac{\sigma_{yp}}{n} \tag{15}$$

BRITTLE MATERIALS. For brittle materials the criteria for working stresses are

$$\sigma_w = \frac{\sigma_{\text{ultimate}}}{K_t \times n} \qquad \text{(tension)} \tag{16}$$

$$\sigma_w = \frac{\sigma_{\text{compressive}}}{K_t \times n} \qquad \text{(compression)} \tag{17}$$

where K_t is the stress-concentration factor, n is the factor of safety, σ_w and τ_w are working stresses, and σ_{yp} is stress at the yield point.

WORKING-STRESS EQUATIONS FOR THE VARIOUS THEORIES:

Stress Theory

$$\sigma_w = \frac{\sigma_x + \sigma_y}{2} \pm \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{18}$$

Shear Theory

$$\sigma_w = 2\sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{19}$$

Strain Theory

$$\sigma_w = (1 - \nu)\left(\frac{\sigma_x + \sigma_y}{2}\right) + (1 + \nu)\sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{20}$$

Distortion-energy Theory

$$\sigma_w = \sqrt{\sigma_x^2 - \sigma_x\sigma_y + \sigma_y^2 + 3\tau_{xy}^2} \tag{21}$$

Strain-energy Theory

$$\sigma_w = \sqrt{\sigma_x^2 - 2\nu\sigma_x\sigma_y + \sigma_y^2 + 2(1 + \nu)\tau_{xy}^2} \tag{22}$$

where σ_x, σ_y, τ_{xy} are the stress components of a particular point, ν is Poisson's ratio, and σ_w is working stress.

24. STRENGTH REDUCTION

If the loads acting on a member are cyclic with respect to time, the stress-concentration factor described in Article 22 can no longer be applied. It is now necessary to make fatigue tests on specimens to determine the strength-reduction factor K_f.

DEFINITION OF K_f:

$$K_f = \frac{\text{Endurance limit without stress concentration}}{\text{Endurance limit with stress concentration}} = \frac{\sigma_e}{\sigma_e'} \tag{23}$$

where σ_e = endurance limit stress. It has been found by test that generally for carbon steel $K_t > K_f$, but for alloy steel $K_t = K_f$. K_f has no meaning unless geometry, size, and material of the specimen are stated.

NOTCH SENSITIVITY INDEX. The notch sensitivity index q is a measure of the degree of agreement between K_f and K_t for a particular specimen, or member, of given size and material containing a stress concentrator of given size and shape:

$$q = \frac{K_f - 1}{K_t - 1} \tag{24}$$

Notch sensitivity varies between zero (where $K_f = 1$) and unity (where $K_f = K_t$). In general q is lower for cast alloys than for high-strength wrought materials.

25. FATIGUE WORKING STRESSES

The application of cyclic stress to a member changes the design calculations due to a reduction in the maximum allowable stress. (See Article 18.) In this case the strength theories discussed in Article 21 must be modified to take this into account.

DEFINITIONS:

Stress Cycle. A stress cycle is the smallest section of the stress-time function which is repeated identically and periodically as shown in Fig. 4.

Maximum Stress. $\sigma_{\max}$ is the greatest algebraic value of the stress in the stress cycle, being positive for a tensile stress and negative for a compressive stress.

Minimum Stress. $\sigma_{\min}$ is the smallest algebraic value of the stress in the stress cycle, being positive for a tensile stress and negative for a compressive stress.

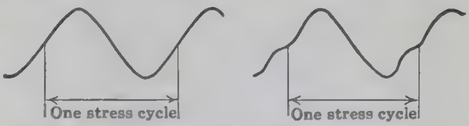

Fig. 4. Definition of one stress cycle.

Range of Stress. σ_r is the algebraic difference between the maximum and minimum stress in one cycle:

$$\sigma_r = \sigma_{\max} - \sigma_{\min} \tag{25}$$

For most cases of fatigue testing the stress varies about zero stress, but other types of variation may be experienced, as shown in Fig. 5.

Alternating-stress Amplitude (Variable Stress Component). σ_a is half the range of stress, $\sigma_a = \sigma_r/2$.

Mean-stress (Steady-stress Component). σ_m is the algebraic mean of the maximum and minimum stress in one cycle:

$$\sigma_m = \frac{\sigma_{\max} + \sigma_{\min}}{2} \tag{26}$$

Stress Ratio. R is the algebraic ratio of the minimum stress and the maximum stress in one cycle.

MODIFICATION OF THE STRENGTH THEORIES:

Stress Theory

$$\sigma_{\max} = (1 - P)\sigma_m \pm \sigma_e \tag{27}$$

where $P = \sigma_e/\sigma_{yp}$. This equation is for normal stresses only where σ_x and σ_y are principal stresses and $\tau_{xy} = 0$.

$$\pm\sigma_e = 1/2\,\{(\sigma_x' + \sigma_y') - (1 - P)(\sigma_x'' + \sigma_y'') \pm \sqrt{[(\sigma_y' - \sigma_x') - (1 - P)(\sigma_y'' - \sigma_x'')]^2 + 4[\tau_{xy}' - (1 - P)\tau_{xy}'']^2}\} \tag{28}$$

Shear Theory

$$\pm\sigma_e = \sqrt{[(1 - P)(\sigma_x'' - \sigma_y'') - (\sigma_x' - \sigma_y')]^2 + 4[(1 - P)\tau_{xy}'' - \tau_{xy}']^2} \tag{29}$$

Distortion-energy Theory

$$\sigma_e = \sqrt{(\sigma_x')^2 - \sigma_x'\sigma_y' + (\sigma_y')^2 + 3(\tau_{xy}')^2} - (1 - P)\sqrt{(\sigma_x'')^2 - \sigma_x''\sigma_y'' + (\sigma_y'')^2 + 3(\tau_{xy}'')^2} \quad (30)$$

Strain-energy Theory

$$\sigma_e = \sqrt{(\sigma_x')^2 - 2\nu\sigma_x'\sigma_y' + (\sigma_y')^2 + 2(1 + \nu)(\tau_{xy}')^2} - (1 - P)\sqrt{(\sigma_x'')^2 - 2\nu\sigma_x''\sigma_y'' + (\sigma_y'')^2 + 2(1 + \nu)(\tau_{xy}'')^2} \quad (31)$$

In the foregoing equations σ_e = endurance limit for complete reversal of stress (see Fig. 5), σ_x', σ_y', τ_{xy}' = maximum stress, σ_x'', σ_y'', τ_{xy}'' = mean stress, $P = \sigma_e/\sigma_{yp}$, σ_{yp} = stress at yield point, ν = Poisson's ratio. For further information see Ref. 2.

FIG. 5. Possible variations of stress with time.

Working Stresses can be determined by substituting the expression $P\sigma_w$ for σ_e in eqs. 27 to 31 and solving the equation for σ_w. By doing this, σ_w can be considered as an equivalent allowable simple static stress.

FIG. 6. Modified Goodman diagram.

Goodman Relation. It is possible by means of a simple relationship to represent all possible combinations of fluctuating stress. It has been shown that the maximum tensile or compressive stress to which a member may be repeatedly subjected without causing fracture depends on the range of stress applied. The modified Goodman relation as shown in Fig. 6 can be used to predict either the cyclic stress σ_a or the mean stress σ_m which can be applied to the specified material. σ_m or σ_a for the respective cases must be known.

26. EXPERIMENTAL STRESS ANALYSIS

The determination of static and dynamic strains in specimens and machine parts by means of physical measurements is defined as *experimental stress analysis*. Direct strain measurements are made possible by mechanical and electrical pickup devices. Mechanical and optical levers, brittle lacquers, photogrids, and cathetometers are mechanical systems. Electromagnetic, resistance, and capacitance methods are forms of electrical systems. Sometimes the nature of the installation and the operating conditions preclude direct strain measurements. Indirect methods such as high-speed photography of body displacements and velocity or acceleration measurements by means of moving coil pickups have proved to be acceptable. (See Section 18.)

DIRECT STRAIN MEASUREMENTS

Bonded wire strain gage (Fig. 7) consists of a grid of strain-sensitive wire protected by a paper sheath and cemented to the specimen. A change in the length of the grid due to strains in the specimen changes the resistance of the wire. This change in resistance is readily measured by means of suitable electrical circuits. The gage is suitable for measurement of dynamic as well as static strains.

Mechanical strain gage is used to measure static strains in a specimen under load. The instrument employs either the optical or the mechanical lever system to multiply the strain, which then may be read from a suitable scale.

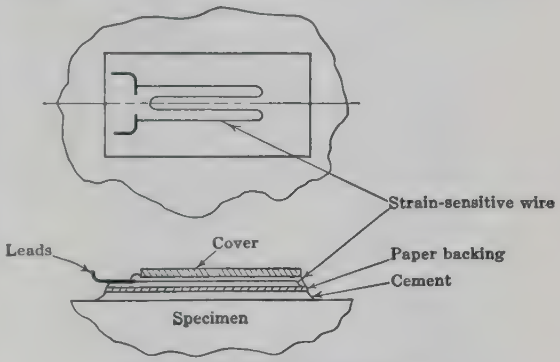

Fig. 7. Bonded wire strain gage.

Magnetic strain gage is based on the principle of a change in either self or mutual inductance of the gaging element. The simplest type is the variable inductance gage where the change in an air gap in a magnetic circuit varies the permeance of the circuit, thus giving an indication of the strains produced. See Fig. 8. This gage is used to measure both static and dynamic strains.

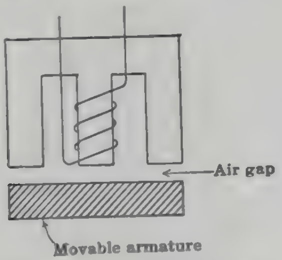

Fig. 8. Magnetic strain gage.

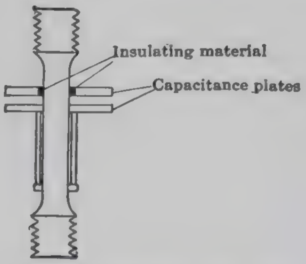

Fig. 9. Capacitance strain gage.

Capacitance strain gage is based on the principle of variation of capacitance by separation of elements, change in area of elements, or change in specific inductive capacity of a dielectric. The first of these methods (Fig. 9) is the most widely used, and the gage is so attached to the specimen that the strain produced causes a separation of the two plates. This type of gage is applicable for measuring both static and dynamic strains.

Acoustic strain gage employs a taut wire between two points mounted on the specimen, as shown in Fig. 10. The strain produced in the specimen alters the tension in the wire, thus changing its natural frequency. The natural frequency of the wire is determined by a variable frequency oscillator. Resonance is indicated by the output meter of the unit. By suitable methods the strain can be computed. This gage is suitable for measuring static and dynamic strains.

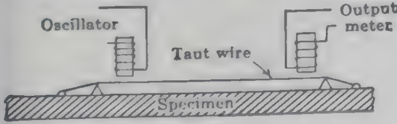

Fig. 10. Acoustic strain gage.

Brittle lacquer coatings are very convenient as they graphically present an overall strain picture, including the principal strain directions. They are revealed by cracks produced in the coating due to the strain in the specimen. The method consists of coating the specimen with lacquer, which becomes brittle on hardening. When the strains in the piece reach a prescribed magnitude, the lacquer cracks. This method, which gives quan-

titative results accurate to within ±10%, can be used to detect static and dynamic strains in tension or compression.

Photogrid method consists of coating the specimen with a photosensitive film on which a grid system is printed. The dimensional change in the grid system under load is a measure of the strain produced. This method is suitable for measuring permanent static strains only.

Cathetometer method consists of measuring the relative movement of two points on a test specimen under load by means of a microscope with a vernier scale attachment. Both static and dynamic strains can be measured by this method.

INDIRECT STRAIN AND DISPLACEMENT MEASUREMENTS

Displacement pickups are used to detect the motion or displacement of the specimen. In general they consist of a seismic mass-spring system having suitable dynamic characteristics. The motion of the seismic element is used to produce an electrical signal by any of the electrical methods just described.

Velocity pickups usually employ the principle of a moving permanent magnet within a coil whose field strength is constant. The voltage induced in the coil is proportional to the relative velocity of the magnet and coil. By mechanical modification, the arrangement can serve as a generator where the voltage output is proportional to the velocity of the moving coil, as shown in Fig. 11. This pickup can be used to measure dynamic strains. By electrically integrating the output, a signal proportional to displacement can be obtained.

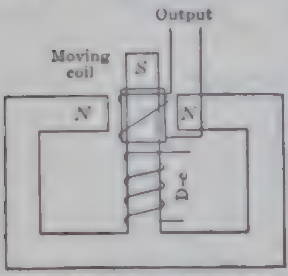

Fig. 11. Velocity pick-up.

Acceleration can be detected by pickups similar to those used for displacement and velocity. The output can be integrated for convenience. In some designs the system consists of a piezoelectric crystal which, by virtue of its high natural frequency, permits the detection of sharp transients and high frequency accelerations.

Photoelastic methods involve the construction of a model of the prototype from an isotropic transparent material such as bakelite, celluloid, and glass. When these substances are subjected to stress they become doubly refracting, and plane polarized light on passing through the material is changed into two component mutually perpendicular rays which are parallel and perpendicular to the directions of stress. The emergent rays will be out of phase, depending on the stress and the thickness of the material. A photograph of the emergent rays gives light and dark fringes indicative of the distribution of the principal stresses. A schematic diagram of one method is shown in Fig. 12. This procedure is used to measure static stress.

TESTING OF MATERIALS

27. TESTING MACHINES

Machines for testing materials are of varying construction and capacity for testing specimens in tension, compression, torsion, impact, fatigue, and other specific purposes. Usually the mechanism for applying the load to the specimen is independent of the weighing apparatus. By this arrangement, the accuracy of the weighing is not affected by the deformation of the specimen which takes place as the load is applied.

TENSILE TESTING MACHINE, SCREW TYPE. This type of machine is in common use in the United States. It may be used for either tension or compression testing. The stress on the test piece is produced through the movement of platforms by screws, which, depending on the direction of turning, will either separate the platforms or draw them toward each other. A compound lever system transmits the platform force to a weighing beam kept in balance by moving the poise. Machines of this type are built by the Tinius Olsen Company in Philadelphia, Riehle Brothers in East Moline, Illinois, and Baldwin Southwark in Philadelphia.

TENSILE TESTING MACHINE, HYDRAULIC TYPE. A direct-acting hydraulic tensile testing machine has a head moved by hydraulic pressure, intensity of which is read on a pressure gage. The load on the test piece is determined by multiplying the pressure reading by a constant which depends upon the area of the cylinder. These machines are manufactured by Riehle in East Moline, Illinois, and Baldwin Southwark in Philadelphia.

TENSION CREEP-TESTING MACHINES. Since creep testing involves considerable time, most machines are built for multiple testing, and the tests can be carried out at any desired temperature. The test specimens are supported on knife edges at the top and loaded by lever systems. A common way to obtain the creep deformation is by a micrometer microscope.

TORSION-TESTING MACHINES. A torsion-testing machine consists essentially of a turning head which applies a torque to a test specimen. This torque is transmitted through a lever system to a hydraulic gage, the reading of which indicates the applied twisting force or torque. The angle of twist is measured directly on the turning head of the machine. The angle through which the specimen twists is recorded for each increment of torque until rupture occurs.

IMPACT-TESTING MACHINES:

Drop-weight Machines. The impact is obtained by a hammer of known weight falling from a predetermined height on the specimen. In one type of machine the absorption of kinetic energy by the specimen is determined from the deflection of a spring.

Charpy Pendulum Machine. This machine is used for testing small notched specimens for energy absorption (Fig. 1). The specimen is placed horizontally with the ends supported by an anvil. The hammer strikes the specimen midway between the supports opposite the notch. The energy expended in fracturing the specimen is the product of the weight of the pendulum and the difference between its height of fall and height of rise. This energy is expressed either in foot-pounds or in kilogram-meters.

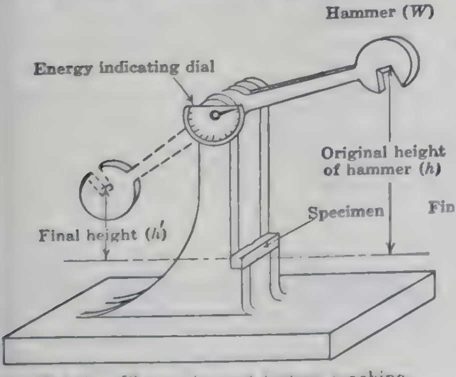

Fig. 1. Charpy impact testing machine.

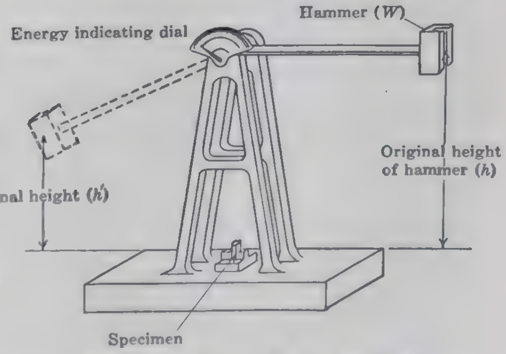

Fig. 2. Izod impact testing machine.

The Izod machine is used for testing a notched specimen for energy absorption. The specimen is supported at its lower end in a vertical position as a cantilever (Fig. 2). The pendulum strikes the specimen at a definite distance above the notch on the same side as the notch. The energy used in breaking the specimen is the product of the weight of the pendulum and the difference between its height of fall and height of rise. This energy, expressed in foot-pounds, is known as the Izod value.

The rotary hammer impact machine is used to determine energy absorption of a test specimen. This is accomplished by means of a flywheel to which is attached a knife that can assume two positions, either flush with the rim of the wheel or projecting from the rim of the wheel. The latter position is required for breaking the test piece. The energy expended by the flywheel in breaking the specimen is measured by a tachometer tube.

The high-impact shock-testing machine consists of a large hammer hinged to swing in an arc (Fig. 3). It strikes the lower surface of a large anvil table on which equipment to be shock tested is mounted. This machine is used for determining the vibratory motion and stresses set up in a piece of equipment under impact conditions.

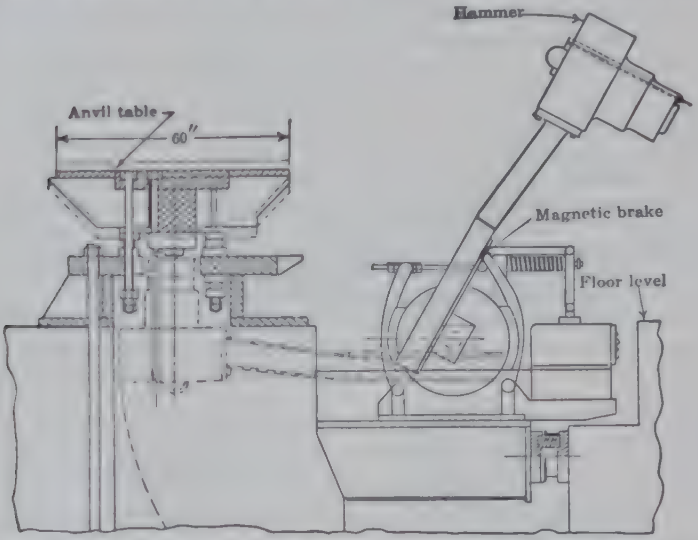

FIG. 3. High impact shock-testing machine for medium-weight equipment.

HARDNESS-TESTING MACHINES (See also Section 1, Article 10):

The Brinell hardness-testing machine is used to measure the resistance of the material to the penetration of a hardened steel ball subjected to a standard load. The diameter of the indentation produced is measured with the aid of the microscope. A Brinell hardness number can be calculated or read from standard tables, and is used as a comparative measure of the hardness of materials.

The Rockwell hardness-testing machine is a direct-reading indentation type of machine where the ball or diamond point is impressed into the material. The Rockwell hardness number is read from the dial.

The Vickers hardness-testing machine follows the indentation principle, where, in this case, a pyramidal diamond indenter and standard load is used. A microscope measures the diagonal of the indentation, and the Vickers hardness number is either computed or read from prepared charts.

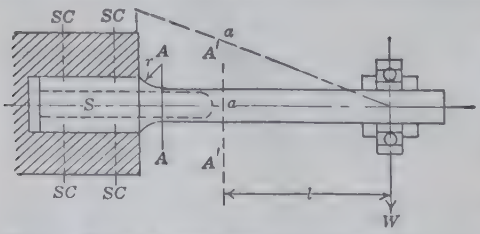

FIG. 4. Rotating cantilever bar fatigue test specimen.

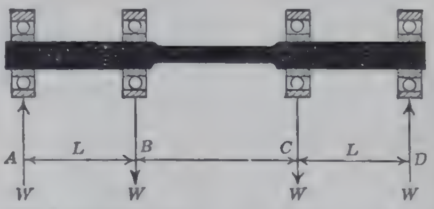

FIG. 5. Rotating beam bar fatigue test specimen.

The Shore scleroscope is a machine which measures the rebound of a falling weight dropped on the specimen. It is used primarily to give comparative values for checking uniformity of a product in production.

The Tukon hardness machine is a sensitive indenter type of machine of particular value in measuring hardness on individual grains and of certain small areas of specimens where the hardness of a zone having a certain microstructure is desired.

FATIGUE-TESTING MACHINES are classified as (*a*) rotary bending, (*b*) plane bending, (*c*) direct stress, and (*d*) torsional stress.

The rotary bending machine is the most widely used and the simplest type of fatigue-testing machine in which the specimen is in the form of a rotating bar. The rotating cantilever or the rotating beam form of loading may be applied. Figure 4 shows one of the modern forms of a rotating cantilever bar. The cantilever bar is end-loaded through a ball-bearing cage. In the rotating beam method the specimen is four-point loaded through ball bearings, as shown in Fig. 5. Machines are built to operate at speeds up to 30,000 rpm.

The plane bending machine subjects the specimen to reversed bending without rotation. The specimen is forced to vibrate by induced magnetism from electromagnets (Fig. 6). Frequencies up to 17,000 cpm have been employed.

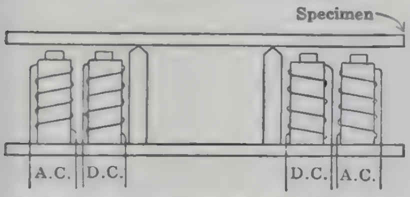

Fig. 6. Plane bending fatigue machine.

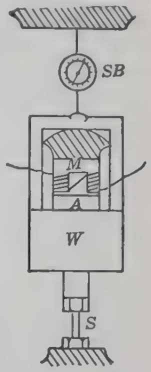

Fig. 7. Direct-stress fatigue machine.

The direct-stress method subjects the specimen to repeated tensile stress by means of the electromagnetic principle. A typical machine is shown in Fig. 7.

The torsional-stress machine applies repeated torsional stress to a specimen by means of inertia or resonant methods. Figure 8 shows a machine of the former type.

DAMPING-TESTING MACHINES. One type of machine used to determine the damping capacity of metals (Fig. 9) consists of a cylindrical specimen held rigidly at one end while a torque is applied to the opposite end. When the specimen is released, a record of its vibrations with time is made on sensitized photographic paper.

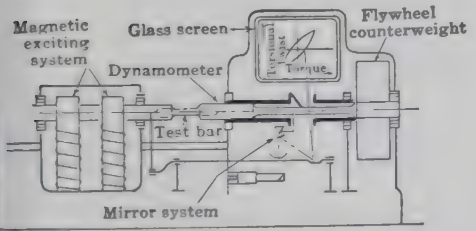

Fig. 8. Inertia torsional fatigue machine.

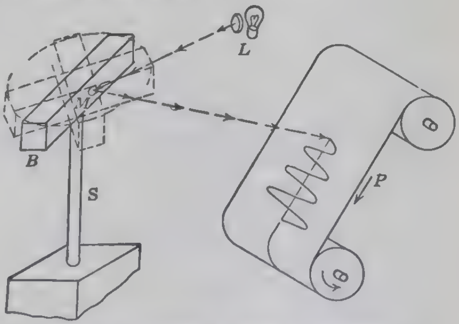

Fig. 9. Damping capacity machine.

28. STANDARD TEST PIECES

The fundamental data obtained in a test on material are affected by the method of testing and the size and shape of the specimen. To eliminate variations in results due to these causes, standards have been adopted by the ASTM, the ASME, and various associations of manufacturers. (See ASTM, ASME, etc., Standards for details.)

SPECIMENS FOR TENSION TESTS. Figure 10 shows a group of machined test bars in common use for testing steels and some nonferrous metals. The most common one, specimen *A*, is often referred to as the Standard 505 specimen. Its diameter is chosen to give a 0.2-square-inch area of section which is convenient in that the load in pounds on the specimen at any time during test can easily be converted to stress (pounds per square inch) by multiplying by 5. The sub-size specimens (*B* to *E*) are used when the size of material available will not permit the use of specimen *A*. In all specimens, however, it can be noted that the gage length (G.L.) over which the elongation measurements are taken is about four times the diameter of the reduced section. By keeping this similarity of specimens, the data obtained are reasonably comparable to those obtained on specimen *A*.

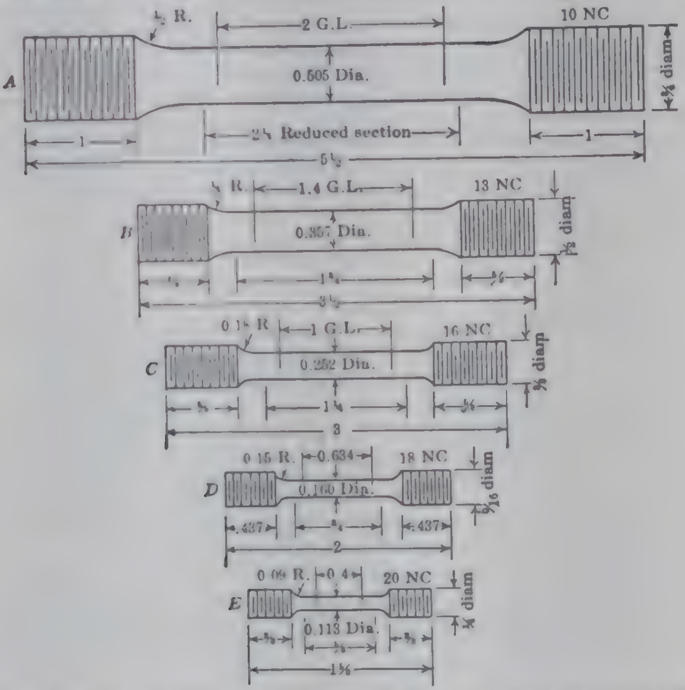

Fig. 10. Standard and subsize machined test specimens for cast, rolled, and forged steels, and nonferrous alloys.

Standard test bars for cast iron are shown in Fig. 3, p. 19-08, where specimen *A* is for malleable iron. Specimen *B* is the most common of the three standard test bars used for determining the properties of gray and alloy cast irons.

BEND-TEST SPECIMENS (ASTM Standards E16-39). Rectangular specimens with widths at least one and one-half times the thickness are used, the edges being smoothed so that the fracture will not take place at the edge. A radius up to one-eighth the thickness of the specimen may be used on the edges. The outside surfaces of the specimen must be smooth and free from local defects and transverse scratches. The length, which may vary with the thickness of the piece, is unimportant provided it is long enough to perform the bending operation.

COMPRESSION-TEST SPECIMENS (ASTM Tentative Standards E9-46T). It is recommended that standard compression-test specimens be in the form of circular cylinders and that the ends of the specimens shall be plain and normal to the longitudinal axis of the specimen. There are three types of compression-test specimens for metallic materials (short specimens, medium-length specimens, and long specimens). Short specimens are used for compression tests of such metals as bearing metals, which in service are used in the form of a thin plate or shell to carry load perpendicular to the surface. Medium-length specimens are used for determining the general compressive strength properties of metallic materials. Long specimens are best adapted for determining the modulus of elasticity in compression of metallic materials. Suggested dimensions for compression test specimens for general use are given in Table 1.

Table 1

	Diameter, *d*, in.	Length, *l*, in.
Short specimen	1 1/8 ± 0.01	1 ± 0.05
Medium-length specimens	0.798 ± 0.01	2 3/8 ± 1/8
	1 ± 0.01	3 ± 1/8
	1 1/8 ± 0.01	3 3/8 ± 1/8
Long specimens	0.798 ± 0.01	6 3/8 ± 1/8
	1 1/4 ± 0.01	12 1/2 min

IMPACT-TEST SPECIMENS (ASTM Tentative Standard E23-41T). The simple-beam (Charpy type) specimen and the cantilever-beam (Izod type) specimen are shown in Figs. 11 and 12, for use in the Charpy type and Izod type impact machines, respectively.

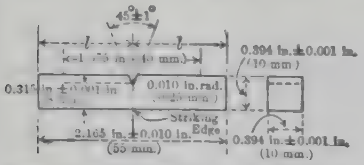

Fig. 11. Simple beam (Charpy) impact-test specimen.

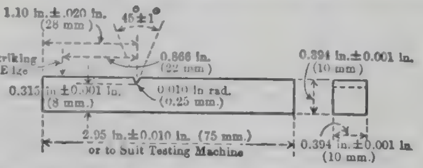

Fig. 12. Cantilever beam (Izod) impact-test specimen.

FATIGUE-TEST SPECIMENS. No specifications have been drawn up for standard fatigue test bars.

29. NONDESTRUCTIVE TESTING METHODS

Nondestructive testing is descriptive of test and inspection methods which, when applied to materials for purposes of detecting mechanical defects, variations in metallurgical condition, or composition do not impair the usefulness of the material or part.

SPARK TEST. The spark test is used to check material for chemical analysis. Since the sparks emitted from material when held to an abrasive wheel have a characteristic color, depending on the elements present in the steel, it is possible to classify unknown material rapidly by recognizing the color pattern produced.

RADIOGRAPHIC INSPECTION. The x-ray, because of the short wave length, can penetrate opaque materials; the depth of penetration depends upon the power of the x-ray beam. The sensitivity of the process is the ability of the method to reveal defects whose thickness or depth is expressed as a percentage of the metal thickness encountered. In other words, a sensitivity of 2% means that the defect revealed is $0.02t$ in depth, where t = metal thickness.

X-ray Radiography. When the x-ray passes through the material to the opposite side on which a special type sensitive film emulsion has been placed, a shadow picture is obtained wherein changes in density or thickness are revealed by light and dark areas. Voids, cracks, and holes appear as dark areas because they permit more rays to penetrate through them in a given time interval. This method of analysis is useful in checking welds, castings, forgings, plastic parts, and assemblies. Radiography can be used on light alloys, steel, other metals, and plastics. Under careful control a sensitivity of 2% is readily obtained which meets the requirements of the ASME boiler code. The standard equipment can be used for materials up to one foot thick.

Gamma-ray Radiography. Radium salts emit gamma-rays which are similar to x-rays but have a shorter wavelength, hence a greater penetrating power. Their advantage is that tests can be made without much expense since a capsule of radium salt is all that is required aside from the photographic equipment. The sensitivity is not so high as that of the x-ray for thicknesses less than 2 in. In general the sensitivity is approximately 3%.

Fluoroscopic Inspection. If the x-rays on emerging from the object being tested are allowed to fall on a fluorescent screen, an observer can view the shadow pattern directly. This procedure saves the time and expense of photographing the result. These units are particularly adaptable to conveyor feed systems. A sensitivity range of 5 to 15% is possible.

X-ray Diffraction. The nature and behavior of most substances depend on the arrangement of atoms and molecules in the structure. One of the properties of a material is its diffractive effect produced by x-radiation. Thus, if a beam of x-rays is passed through a crystal the beam will be bent, or redirected, into a series of emergent rays whose separation and intensities are characteristic of the material. With radiographic film a record is obtained of the location and intensity of the diffracted rays. These form a *fingerprint* of the substance, so called, because no two substances have been found to produce identical diffraction patterns. This fingerprint makes possible prediction of the behavior of substances when subjected to various treatments and also identification of what has happened to the substance up to the time of making the diffraction test.

This method is useful in determining the preferred crystal orientation, in deriving specifications for new materials, in discovering whether a steel has been adequately annealed for machining, in determining quality of case hardening, and in giving a quick and exact identification of a material and its prior processing.

MAGNETIC-PARTICLE INSPECTION. Although radiographic inspection will find deep-seated irregularities, other methods are required to find nonvisible, close-lipped discontinuities at or near the surface. The following types provide indications of cracks, semi-cracks, inclusions, and pores which may give rise to fatigue failures by acting as stress raisers.

Magnaflux Inspection. When a magnetic material is magnetized, discontinuities give rise to localized leakage fields which are revealed by the attraction of finely divided magnetic particles sprinkled on the material. There are two types of inspection media. In the wet method, the magnetic particles are prepared in paste form and mixed with oil. This method is more sensitive to minute surface discontinuities. In the dry method, which is more sensitive to subsurface discontinuities, magnetic powder is dusted on the magnetized material. Both direct and alternating currents are used for magnetization. The direct current is useful in finding significant subsurface discontinuities and is used for inspection of welds and castings. Because of *skin effect* the alternating current is limited to surface or very near surface discontinuities and is used for inspection of highly finished machine parts.

Magnaglo Inspection. This method employs fluorescent magnetic particles suspended in oil which give better contrast and extreme sensitivity. It is useful for material of complex contours such as splined shafts and milling cutters.

Zyglo Inspection. This fluorescent penetrant suspended in oil is used to determine discontinuities in nonmagnetic materials. Items like ball bearings are more easily inspected by this method. The material is usually dipped into the penetrant, which penetrates the very fine cracks. When viewed under "black" light the discontinuities are revealed.

SUPERSONIC INSPECTION. Longitudinal sound waves of extremely short wave-length travel through a given material at a velocity corresponding to the density and elastic properties of the substance. Thus a change in velocity or a loss of energy will occur when the sound beam strikes an irregularity such as a crack, separation, inclusion, or blow-hole. By electrical pickup it is possible to detect an irregularity as small as 0.001 in.

Reflectoscope. Internal defects are detected by sending supersonic impulses from a crystal into the material and measuring the time required for these impulses to penetrate the material and be reflected from the opposite side of the defect. The operator views an oscilloscope on which the electrical impulses from the reflected vibrations are impressed. The scanning line indicates the initial impulse, any irregularities, and the back face reflection respectively. The main disadvantage is that the specimens should be finished to about 250 micro-inches rms in order to obtain satisfactory transmission of crystal vibration to the material. It is suitable for metals up to 28 ft thick, but plastics can be tested only to a thickness of 3 in. If plastics have low resin content, the depth is reduced to about $^1/_2$ in. because the material damps out the sound waves used in the test.

Brush Hypersonic Analyzer. This equipment is best suited to detect defects in plates, strips, and sheets. The ray is not reflected in this type, but pickup equipment is necessary on the opposite face. A pen and ink recorder is used to indicate changes in the sound energy picked up by the receiver. In general this test shows only the existence of the separation but not its nature or depth.

Sperry Supersonic Thruray. This equipment is used to compare production units with a standard unit for soundness of spot welds, the occurrence of laminations in sheet products, the quality of bond in bimetals, and the homogeneity of sintered materials. The principle of operation is similar to that described in the foregoing paragraph except that the units must be placed in a sound-transmitting fluid.

SPECTROGRAPHIC EXAMINATION. An accurate analysis of a material can be made rapidly either by spectrography or x-ray spectrometry. It is suitable for checking quality and structure of the material or as an aid in the development of materials and their control in manufacture. The metallic samples can be used as electrodes and an arc, or spark, passed between them. The arc spectrum is then analyzed for the component elements.

MAGNETIC ANALYSIS INSPECTION. The magnetic properties of irons and steels vary with their physical, chemical, and metallurgical properties. Therefore with suitable electronic devices it is possible to obtain comparative indications of structure, analysis, internal defects, case depth, and plating thickness. On bars and tubes defects 0.012 in in depth can be detected.

Cyclograph. A change in structure which results in a significant change in physical properties or any distortion in the crystal lattice will produce some change in the magnetic and electrical properties of the metal. Internal stresses set up during quenching or cold working, residual stresses in shot-peened parts, and near surface variations in structure can be analyzed. The cyclograph does not reveal cracks and surface discontinuities.

For further information see the paper by Rupert Le Grand, Non-destructive Testing Methods, *American Machinist*, May 23, 1946.

VIBRATION

FREE AND FORCED VIBRATIONS. RESONANCE. It is important to differentiate between free and forced vibrations. Free vibration occurs when the driving force is removed, dying out more or less gradually. Forced vibration is maintained by a driving force. The former has a frequency of its own; the latter can have any frequency, depending on that of the driving force. If the frequency of the driving force is in step with the natural or free period of the vibration, the forced vibration will build up to a large amplitude. The vibrating body is then in resonance with the exciting force.

Any body which vibrates freely when the exciting force is removed illustrates free vibration, i.e., in general, a weight vibrating on a spring. Free vibrations, as such, are not important in vibration prevention. Forced vibrations give trouble if an exciting stimulus is present. Resonant types, where the exciting force is in step with the free vibration period, are the most difficult. Knowledge of free vibration period thus is important. An example of a forced vibration is an unbalanced rotor which quivers at all speeds because of unbalanced centrifugal force; the frequency always equals the speed frequency. If speed is in step with the free vibration frequency of the rotor between bearings, vibration will reach a peak value and illustrate resonance. All critical speed vibrations are resonant. Calculation of critical speeds is the determination of free vibration periods to which the body resonates.

1. VIBRATION-FREQUENCY CALCULATION

The following simple cases of calculation of natural vibration frequency are given for reference. Two basic formulas are:

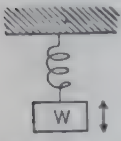

FIG. 1. Linear vibration.

Linear vibration for spring-supported weight (Fig. 1):

$$f = \frac{1}{2\pi}\sqrt{k/M} \tag{1}$$

Torsional vibration for disk on rod (Fig. 2):

$$f = \frac{1}{2\pi}\sqrt{L_1/I} \tag{2}$$

where f = frequency, cycles per second; M = mass, pound inch^{-1} second^2 = W/g; W = weight, pounds; g = acceleration of gravity = 386 inches per second^2; k = stiffness constant of spring = force required to stretch it to unit distance, pounds per inch; L_1 = same constant in torsion or torque required to twist spring or rod through 1 rad of arc, inch-pounds per radian; I = moment of inertia, pound-inch second^2 = WR^2/g; W = weight of body, pounds, executing torsional vibrations; R = radius of gyration, inches. Equation 1 is used more often than eq. 2, as most problems involve linear, rather than torsional, vibrations.

By substituting the value of g for the inch-pound-second system, eqs. 1 and 2 reduce to:

Linear vibrations:

$$f = 3.13\sqrt{k/W} \text{ cps} \tag{3}$$

Torsional vibrations:

$$f = 3.13\sqrt{L_1/WR^2} \text{ cps} \tag{4}$$

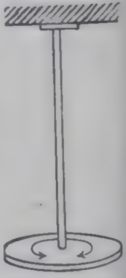

FIG. 2. Torsional vibration.

GRAVITY DEFLECTION FORMULA. For a spring carrying a weight (Fig. 1) causing extension d of the spring, elastic constant k must equal W/d = weight per unit deflection. Substituting this in eq. 3,

$$f = 3.13\sqrt{1/d} \tag{5}$$

where f = cycles per second and d = inches deflection. Thus, if a weight causes an elastic support of relatively small weight to deflect downward through d inches, eq. 5, at once gives the up-and-down frequency. This formula is useful for quick, approximate estimates of certain vibration frequencies. Thus, a shaft carrying a relatively heavy flywheel has a deflection of d. The frequency and the critical speed (see p. 9-13) can be estimated without knowing weight of the flywheel. d is the deflection under one times gravity acceleration. When the system is subjected to accelerations of x-times gravity, the deflection of the system equals x times d.

TRANSVERSE VIBRATION OF UNIFORM BARS. For any vibrating bar of uniform cross section, the frequency is given by

$$f = (a/l^2)\sqrt{EI/W} \qquad (6)$$

where a depends on shape of bar and how it is supported, and l = length, inches. For values of f, see Table 1. In this table, I = moment of inertia of cross section inches^4 (not mass moment of inertia); W = weight, pounds per inch; W_1 = weight, pounds per cubic inch; l = length, inches; D = diameter, inches; h = depth, inches; E = modulus of elasticity, pounds per inch^2.

Table 1. Frequencies for Circular and Rectangular Bars

Support and Mode		Uniform Bar, cps	Circular Section, cps	Rectangular Section, cps
Cantilever		$(11/l^2)\sqrt{EI/W}$	$(2.7D/l^2)\sqrt{E/W_1}$	$(3.2h/l^2)\sqrt{E/W_1}$
		$(70/l^2)\sqrt{EI/W}$	$(17.6D/l^2)\sqrt{E/W_1}$	$(20.3h/l^2)\sqrt{E/W_1}$
		$(193/l^2)\sqrt{EI/W}$	$(48D/l^2)\sqrt{E/W_1}$	$(55.7h/l^2)\sqrt{E/W_1}$
Beam supported at ends		$(31/l^2)\sqrt{EI/W}$	$(7.7D/l^2)\sqrt{E/W_1}$	$(8.9h/l^2)\sqrt{E/W_1}$
		$(124/l^2)\sqrt{EI/W}$	$(31D/l^2)\sqrt{E/W_1}$	$(35.8h/l^2)\sqrt{E/W_1}$
		$(278/l^2)\sqrt{EI/W}$	$(69.5D/l^2)\sqrt{E/W_1}$	$(80.4h/l^2)\sqrt{E/W_1}$
Clamped-clamped beam*		$(70/l^2)\sqrt{EI/W}$	$(17.6D/l^2)\sqrt{E/W_1}$	$(20.3h/l^2)\sqrt{E/W_1}$
		$(193/l^2)\sqrt{EI/W}$	$(48D/l^2)\sqrt{E/W_1}$	$(55.7h/l^2)\sqrt{E/W_1}$
		$(379/l^2)\sqrt{EI/W}$	$(94.8D/l^2)\sqrt{E/W_1}$	$(109.5h/l^2)\sqrt{E/W_1}$

* Note that the free-free beam has the same frequencies as the clamped-clamped beam.

TRANSVERSE VIBRATION OF LOADED UNIFORM BARS. Table 2 gives frequencies of loaded bars, where weight of bar is neglected compared with weight it carries. Symbols have same meaning as in Table 1. These formulas are derived from eq. 5 by substituting proper value of d produced by a load W for each case. When weight of bar cannot be neglected, add 23% of weight of bar to W in case of cantilever and 50% of weight of bar in case of beam loaded in center of span.

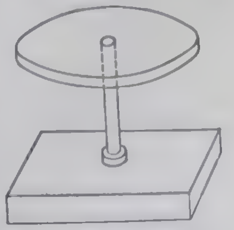

Fig. 3. Vibration of circular disk supported at center.

VIBRATION OF CIRCULAR DISK OF UNIFORM THICKNESS SUPPORTED AT THE CENTER (Fig. 3). Such a plate has exactly the same vibration frequencies as one perfectly free;

Table 2. Vibration of Loaded Uniform Bars

Type of Loading		Frequencies, cps	
		Circular Cross Section	Rectangular Cross Section
Loaded cantilever load on end		$1.2D^2\sqrt{E/Wl^3}$	$1.56\sqrt{Ebh^3/Wl^3}$
Loaded beam loaded in center of span		$4.8D^2\sqrt{E/Wl^3}$	$6.24\sqrt{Ebh^3/Wl^3}$
Loaded beam load off center of span		$1.2D^2\sqrt{\dfrac{El}{Wx^2y^2}}$	$1.56\sqrt{\dfrac{Ebh^3l}{Wx^2y^2}}$

the formula is:

$$f = K(h/r^2)\sqrt{(Eg/W_1)} \tag{7}$$

where h = thickness of disk, inches; r = radius of disk, inches; E = modulus of elasticity, pounds per inch², g = 386 inches per second²; W_1 = weight of disk material, pounds per cubic inch; K = constant depending on the number of nodes n along disk edge; when $n = 4$, $K = 0.25$; $n = 6$, $K = 0.54$. This assumes the absence of ring nodes, which case will be omitted.

LONGITUDINAL VIBRATION OF UNIFORM BARS. Such a bar when clamped on both ends has the vibration frequency:

$$f = (n/2l)\sqrt{(Eg/W_1)}$$

where n = number of half waves along the length and where otherwise the same notations as above are used.

2. VIBRATION MEASUREMENT

A pure sinusoidal vibration is given by any two of the following four quantities: vibration displacement (double amplitude), d; vibration velocity, v; vibration acceleration, a; and frequency, f. They are interrelated by: $v_0 = \pi f d_0$ and $a_0 = 2\pi^2 f^2 d_0$, where d_0, v_0, and a_0 are maximum values. Hence, to measure vibration, any two of these quantities must first be determined; without knowledge of them, quantitative study is impossible. Also, form of path described, i.e., circular, elliptical, etc., and the phase relative to another vibration, sometimes may be necessary. (See Ref. 1.)

VIBRATION DISPLACEMENT MEASURING INSTRUMENTS. To measure displacement, a stationary reference point must be established. This point is either a structure mounted rigidly to the ground or a seismic mass. This is a mass suspended on a spring with a system natural frequency considerably below the vibration frequency. All measurements are being made relative to these points.

When the vibration displacement is above 1/8 in., it can best be measured by placing a ruler parallel to the direction of vibration. In the majority of cases, the vibration is smaller than $1/8$ in.; then the motion must be amplified. This can be done either mechanically, optically, or electrically.

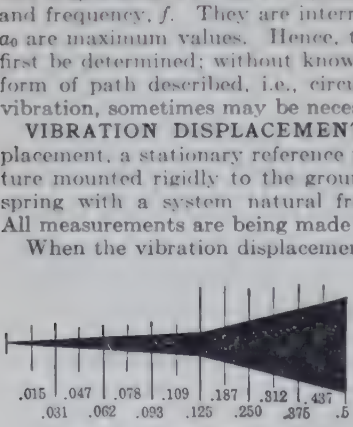

FIG. 4. V-scope.

V-scope. A wedge is printed on a piece of gummed paper approximately 2 in. long and 1/2 in. wide (see Fig. 4). This paper is stuck to the vibrating surface. When the paper vibrates, a blurred triangle-shaped image can be seen. Lines perpendicular to the axis of the wedge are drawn on the paper and marked by figures. The figure on the line going through the apex of the triangle is the vibration displacement. This is probably the simplest and most inexpensive vibration indicator. The stickers are sold in rolls of 1000 by the Avery Adhesive Company in Los Angeles, Calif. They can measure a displacement range of 30 to 500 mils. Their accuracy for their present form and quality of print is within 10 mils below 100 mils, and within 10% above 100 mils. They are very useful for rough measurements on shake tables or other devices vibrating with larger displacements; their application is easy.

Dial-type Displacement Indicator. A dial gage, reading in mils, is set in a hollow block of metal weighing about 2 lb and supported by a spring (see Fig. 5). The axis of the indicator stem passes approximately through the center of gravity of the block. The base of the spring is placed on the vibrating surface with which the indicator stem then makes contact. The stem and the pointer are vibrating with the surface, while inertia keeps the mass and the face of the dial gage stationary. The width of the (blurred) image of the oscillating pointer, read on the mils scale, gives the vibration displacement. Higher accuracy of reading can be obtained when the indicator is observed under stroboscopic light of the vibration frequency.

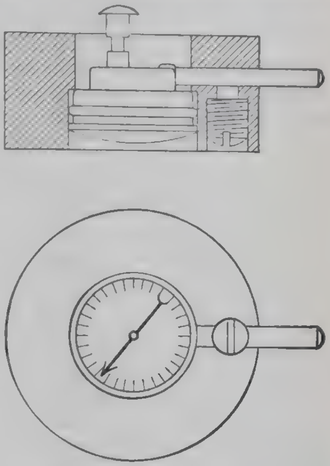

Fig. 5. Dial-type displacement indicator.

This instrument is portable and suitable for factory use where high accuracy is not required; accuracy is approximately 1 mil. Personnel can easily be trained to use this instrument. Its limitations are resonant frequency of the spring-mass system (low frequency limit) and the maximum acceleration which the indicator can follow (giving the maximum displacement for the various frequencies—3 mils at 60 cps, 10 mils at 30 cps, and 100 mils at 10 cps); chatter of the indicator button occurs above this acceleration. In special cases, the amplitude indicator without the inertia part can be rigidly attached to a supporting post if a convenient point of attachment, free from vibrations, is available.

THE VIBROGRAPH will make a complete graphical record of a vibration, giving a permanent record of both frequency and amplitude. The records are traced by means of a fine stylus on moving celluloid film or wax-paper band. Their range is from 0.5 to 125 mils displacement, and up to frequencies of 120 cps. As to limitations, the same considerations as for the dial-type displacement indicator apply, although their range is considerably wider. The mechanical amplification is of the order of 15 to 25, so that a 10 mils displacement vibration traces a sine wave approximately $^3/_{16}$ in. between peaks. A microscope or magnifying glass with a graduated scale is used to read records made of small displacement vibrations (below 10 mils). Vibrographs are very useful where wave shape of vibration or frequency components should be measured, and also to check natural frequencies of structures. They are easier to apply and more portable than electrical instruments, and often give the same information. They are manufactured by Cambridge Instrument Company, London and Cambridge, England; General Electric Company, Schenectady, N. Y., and Westinghouse Electric Corporation, Pittsburgh, Pa.

TORSIOGRAPH. To detect torsional oscillations in a revolving shaft, as a ship propeller shaft, or a Diesel engine shaft governed by a heavy flywheel, a Geiger (marketed by Commercial Engineering Laboratories, Detroit, Mich.), or other torsiograph may be used. This is an inertia instrument comprising essentially one part rigidly attached to the shaft, taking part in its torsional oscillations, and a flywheel, mounted in its own bearings and driven through a flexible spring at the shaft speed. The flywheel maintains substantially constant angular velocity. A multiplying lever mechanism responds to shaft oscillations with respect to the nonoscillating flywheel, and records oscillations in a graph (see Ref. 2). The vibrograph of the Cambridge Instrument Company can be adapted for torsional vibration measurements by addition of a flywheel. Another torsiograph is made by General Motors Research Laboratories, Detroit, Mich. The torsiographs are reported to give satisfactory readings up to approximately 100 cps.

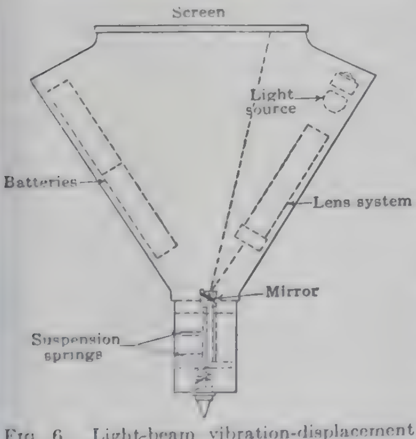

Fig. 6. Light-beam vibration-displacement indicator.

LIGHT-BEAM VIBRATION-DISPLACEMENT INDICATORS. These instruments use optical amplification, are easy to use, have a wide frequency range, and are very accurate. Vibration displacements as small as 0.1 mil can be measured. The indicators are relatively compact and of light weight, and they have been found to be very practical for vibration measurements on rotating machines in the factory as well as in the field. The vibration is transmitted from a stylus to a rotating mirror which reflects the light of a flashlight bulb on a scale engraved into an opaque glass plate. A light band is visible on the scale, and its width is proportional to vibration displacement (see Fig. 6). Light-beam vibration-displacement indicators are being manufactured by the Davey Vibroscope Company, New York, N. Y., and the General Electric Company, Schenectady, N. Y.

ELECTRICAL VIBRATION-MEASURING INSTRUMENTS. These instruments measure vibration displacement, velocity, and acceleration. They consist of a detector unit and an amplifier unit with indicating meter. The amplifier units are provided with an output plug for connecting oscillographs, chart recorders, earphones, or harmonic wave analyzers, so allowing recording or convenient analysis of the vibration. The most commonly used detectors are vibration velocity units and acceleration detectors. Both consist of spring-mass systems, the vibration velocity units working above their natural frequency, the accelerometers below their natural frequency. (See Ref. 3, p. 75.)

Velocity Units. In the vibration velocity unit a voltage proportional to vibration velocity is generated. A coil is attached to the housing of the unit which in turn is mounted to the vibrating surface. This coil moves within the air gap of a magnetic structure energized by a permanent magnet. Magnetic structure and permanent magnet are spring-suspended within the housing, and hence form a stationary reference point when the unit is vibrated. The output of the vibration velocity unit is of the order of 1 to 100 mv for most practical applications. In detectors which measure torsional vibration, the coil is attached to the housing of the detector which rotates with the oscillating shaft, and the permanent magnet and the magnetic circuit are part of a flywheel driven through springs. The flywheel is running at constant speed without any oscillations. The voltage generated in the coil is then proportional to the torsional vibration velocity.

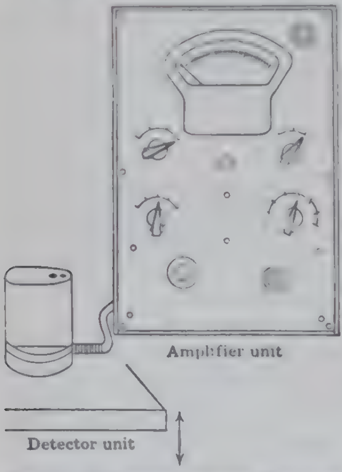

FIG. 7. Vibration velocity detector with amplifier unit for testing gas turbines.

Acceleration Detectors. In an acceleration detector, the mass is accelerated through a relatively stiff spring, whose deflection is proportional to the acceleration. This spring may be a piezoelectric crystal such as quartz, Rochelle salt, or ammonium dihydrogen phosphate (ADP), or a prestressed small-diameter wire ($d = 0.001$ in.) whose resistance is a function of its elongation. The output voltage of both types of detectors can be electrically (single or double) integrated or differentiated; hence measurements of displacement, velocity, or acceleration can be obtained with any of these detectors.

Range. The electrical instruments (see Fig. 7) cover a much wider range of displacement (0.0001 to 0.125 in.), acceleration ($0.01g$ to $5000g$), and frequency (0 to 10,000 cps) than the mechanical vibration instruments described above. They put less load on the vibrating surface, which is important when the mass of the vibrating object is small and when loading might change the vibration characteristic. They are being used where the operator cannot be close to the vibrating surface during its operation, as in airplane or gas-turbine vibration testing, or where permanent records over a longer period of time are required, as for turbine supervisory instruments. Depending on the recorders used, the charts will show either the wave shape of the vibration, or only its average or root mean square value. The output of these detectors is mostly of the order of millivolts, and care should be taken to avoid pickup of extraneous electrical signals. Operators of this equipment should be well trained in their use. Manufacturers are Consolidated Engineering Company, Pasadena, Calif.; General Electric Company, Schenectady, N. Y.; General Radio Company, Cambridge, Mass.; MB Manufacturing Company, New Haven, Conn.; Statham Laboratories, Pasadena, Calif.

Torsional Oscillations. To obtain records of torsional oscillations, it is in many cases possible to use the output of d-c machines which happen to be coupled rigidly to the oscillating shaft and participate in its motion, thus avoiding attachment of additional equipment. Circuit diagrams to be used are shown in Fig. 8. For the use of d-c machines, it is essential that the oscillation frequency be considerably smaller than the commutator ripple frequency. It is evident that direct-current generators can be attached to the shaft for torsional vibration measurements if no other equipment is available. Often this arrangement is more satisfactory than special torsiographs since there is no possibility of exciting and recording the natural frequency of the seismically driven flywheel. The output voltage due to torsional oscillations is proportional to the rated voltage of the machine and the ratio of the vibration velocity to the rotational velocity. This system was found especially useful for determining torsional oscillations of aircraft engines and their accessories.

FIG. 8. Circuit for torsional vibration measurements with d-c machine.

REED FREQUENCY METER. The frequency components of a vibration can be determined with the Frahm tachometer (see Fig. 9). This meter has a large number of reeds carrying masses at their tips, and tuned to respond one after another over a range of frequencies. A convenient model about 6 in. long, made by James G. Biddle of Philadelphia, Pa., covers frequencies of 900 to 30,000 per min by means of three instruments. It is easily portable, readily applied, and shows rapidly varying frequencies as well as more than one frequency at a time if present. Above 30,000 cycles per min (500 per sec), sensitivity is lost because of stiffness of the reeds. For best response the meter should rest solidly against the vibrating body, direction of reed vibration being roughly parallel to direction of motion of exciting vibration. This instrument is an excellent substitute for speed counters and speed tachometers.

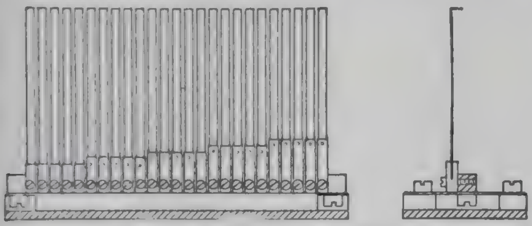

FIG. 9. Frahm tachometer.

To cover a wide frequency range, a number of Frahm tachometers has to be carried. (One tachometer covers approximately one octave.) Frequency meters of more convenient type have only one reed, but that is of adjustable length. The length is adjusted by a frequency calibrated micrometer screw until maximum vibration displacement is obtained. This type of meter is not as easy to use as the multiple-reed meter, but it has the advantage of greater compactness. The adjustable-type reed frequency meters are manufactured by the Davey Vibroscope Company, New York, N. Y., and by Westinghouse Electric Corporation, East Pittsburgh, Pa.

STROBOSCOPE. This device produces intermittent flashes of light. The duration of the flash is very short; the frequency of the flashes can be controlled by a frequency calibrated dial. When the frequency of the flashes is equal to the vibration frequency, the vibrating object appears to be standing still. *Caution:* Objects are also stopped when the flash frequency is a fraction of the vibration frequency. It is good practice to stop the object at several flash frequencies to be sure that the correct frequency is read. Stroboscopes are available from the General Radio Company, Cambridge, Mass., under the trade name Strobotac.

3. VIBRATION EXCITATION

Vibration motors are being used for fatigue testing, determination of natural frequencies and modes of vibration, for acceptance and performance testing where vibration specifications are given, and where vibration is to perform certain processes. Either vibration forces are applied to the object or the object is subjected to a vibration displacement. Vibration forces are applied by electromagnets or unbalanced rotating masses; the object is subjected to vibration displacements when it is attached to a vibrating platform. (See Ref. 1.)

MECHANICAL VIBRATION MOTOR. Exciters which apply vibration forces consist of one or two rotating unbalanced masses. The bearings supporting these masses are bolted to the object to be vibrated. The vibrating forces are uniform in one plane, but not in one direction, if only one unbalanced mass is being used. To obtain vibratory forces in only one direction, two unbalanced masses rotating in opposite directions must be used.

Vibrating platforms on which objects under test can be placed are driven by electric motors through crankshafts, scotch yokes, or eccentric drives. The mechanical vibration motors can be built to apply relatively large forces, and are therefore suitable to vibrate heavy objects. They are limited at the present in their upper frequency range to 60 cps. The wave shape of the vibrations of these machines often becomes poor after some use, because of damaged bearings caused by the high vibratory forces. These motors are manufactured by the Baldwin Southwark Company, Philadelphia, Pa., and by the American Machine and Tool Company, Chicago, Ill.

ELECTROMAGNETIC VIBRATION MOTOR. Some of these motors are built like electrodynamic loudspeakers, their a-c coils connected to power amplifiers which in turn are controlled by variable frequency oscillators. The vibratory force which can be obtained from these motors is often limited by the strength of the driving coils (approx. 400 lb. Objects under test can be placed directly on the motor or connected to the moving coils by means of a connecting link. This practice is being used for vibration testing of aircraft wings.

Another type of electromagnetic vibration motor employs an electromagnet whose poles are applied to the surface of the object under test. This method is especially useful for finding resonant frequencies in structures. When the surface of the structure is nonmagnetic, this method can still be applied when a strip of magnetic material is cemented to the surface. This method has been successfully used to determine resonant frequencies as high as 30,000 cps. A beam supported at its nodal point and excited by an electromagnet is being used to calibrate high *g* accelerometers. Vibration accelerations as high as 800*g* have been obtained at the ends of the beam.

Frequency and amplitude control is continuous and simple and is achieved by changing the oscillator controls. Frequencies can be held very accurately and can be closely adjusted, which is of importance for natural frequency testing of low damping mechanical structures. Fine adjustment of frequency is often difficult to achieve on mechanical vibration motors because energy is stored in the moving parts. Fatigue-testing machines to vibrate test specimens and special structures such as turbine blades or airplane propellers have been built using electromagnetic drives. Electromagnetic vibration motors can be obtained from the General Electric Company, Schenectady, N. Y., the Westinghouse Electric Corporation, East Pittsburgh, Pa., and MB Manufacturing Co., New Haven, Conn.

PNEUMATIC VIBRATION EXCITATION. An air stream is blown through a nozzle against the vibrating object which, in itself, functions as a valve. The air stream hits the specimen and bends it away from the nozzle; the specimen snaps back because of its elasticity, and the cycle is repeated. The frequency is equal to the resonant frequency of the specimen. Good stability and large amplitudes are obtained when the air column connected to the nozzle is tuned, like an organ pipe, to the frequency of the specimen. A piston-shaped armature attached to the specimen will improve performance. A fatigue-testing machine manufactured by the General Electric Company uses an arrangement with two nozzles located on each side of the specimen. These two nozzles are interconnected by a resonating air column. Force is applied to the specimen during each half cycle.

VIBRATION PREVENTION

Of the several methods of attack in vibration reduction the particular method or methods adopted depend on the individual problem. These methods are described briefly here.

REMOVAL OF EXCITING CAUSE. This method, when possible, is most satisfactory. Unbalance in rotating machinery is a common source of trouble. In rigid rotors it can be almost completely eliminated by balance weights. Gear-tooth frequency noise is best avoided by precision in manufacture.

TUNING is applicable only when vibration is distinctly of resonant type. Resonant vibrations usually are excited by a relatively small stimulus, which happens to be in step with a natural vibration frequency. The tuning of steam-turbine wheels is an example, as is also the avoidance of shaft critical speeds through selection of proper diameter at the operating speed.

ELASTIC SUSPENSION can be applied to two different problems. The first problem is the reduction of the forces transmitted by rotating or reciprocating machines, etc., into their bases. Industrial presses, for example, may be elastically mounted to prevent shaking of the building. The second problem is the vibration isolation of apparatus, such as isolation of delicate measuring equipment installed on a vibrating floor, or the isolation of car bodies from the movements of the wheels.

It should be noted that this type of isolation system does not necessarily have to absorb energy, as in case of friction damping. Springs (helical springs, rubber, etc.) put a high reactance (the same as an inductance in an electrical circuit) in the way of the energy flow, and hence prevent it from passing through the mount. The spring suspension of a railroad car isolates from the car body forced vibration imparted to the wheels; the leaf spring contains some friction damping which eliminates resonant bouncing, but has no part in isolation. It can be shown that such friction in springs and shock absorbers somewhat increases forced vibration transmission. The amount of increase is small, even when friction is considerable. Friction is necessary to avoid building up resonant vibrations.

An incorrectly designed elastic suspension may do more harm than good. The design of a good suspension is not always an easy matter and often requires knowledge of vibration principles as well as experience.

DAMPING, or reduction of vibration amplitude through action of friction, is a cure for resonant vibrations only. Forced vibrations are likely to result from powerful exciting forces which are not much reduced by application of friction devices. For example, gear-tooth frequency hum or whistle is a forced vibration, which is reduced but little by stuffing the wheel with a nonresonant damping substance with internal friction. On the other hand, the resonant ring of the wheel, because of its natural periods, may be greatly reduced by such treatment. Shock absorbers used in vehicle suspension are typical friction dampers which limit the amplitude of resonant vibrations excited by road irregularities.

4. REMOVAL OF EXCITING FORCE

MECHANICAL BALANCE OF MACHINERY. It is possible mechanically to balance completely any rigid rotor, whatever may be its unbalance or its shape, by only two weights. The problem is to determine the position and the size of these two weights. Balancing machines make this determination; trial-and-error methods will generally waste money. Balancing of rotors that cannot be considered rigid is a fine art and requires experienced operators.

STATIC AND DYNAMIC BALANCE. Mechanical unbalance in a rigid rotor always can be completely represented schematically as in Fig. 10. The weight A takes account of displacement of the center of gravity of the rotor from its true axis; weights B and C represent a couple, depending on how much the rotor is cocked or twisted sideways from its true axis. The three weights can be replaced by two by splitting A into two parts, placing one in the plane of B and the other in the plane of C. The two weights in each of these planes can then be replaced by a single one in each plane by applying the parallelogram of forces (centrifugal forces in this case). (See Ref. 4, pp. 85-94, and Ref. 2, pp. 62 ff.) That part of unbalance represented by A, Fig. 10, is static unbalance; it can be detected by a static or a gravity test by placing the rotor on ways and noting its heavy spot. The part represented by weights B and C is dynamic unbalance; it can be detected only by a rotational or dynamic test which develops a centrifugal couple. A rotational test, however, does not separate dynamic from static unbalance, but combines the effect of both; otherwise, mechanical balance would be comparatively simple. For this reason, specially designed machines and special methods described below must be used to determine the amount and position of balance weights.

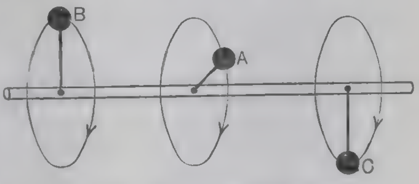

FIG. 10. Mechanical unbalance.

BALANCING MACHINES. Two types of balancing machines are available, stationary machines and portable machines. Stationary machines are used mostly for production balancing. Good general-purpose machines are marketed by the Gisholt Machine Company, Madison, Wis., and the Tinius Olsen Company, Philadelphia, Pa. A balancing machine designed especially for automobile wheels is made by the Bear Manufacturing Company. In many cases special machines are built to handle special jobs. They range from relatively simple machines indicating angular position and magnitude of balancing weights to rather complex automatic machines which balance rotors by drilling holes of the correct depths at the correct angular position.

Portable machines are being used to balance rotors in their final installations and under their actual operating conditions. They are also used for production purposes where the rotor is of such a size that it is not economical to build special bearings for the balancing operation. Portable machines have the disadvantage of requiring more time than the stationary machines to obtain the amounts and the angular positions of the balancing weights. It is the advantage of the portable machines that they balance the rotor under actual operating conditions which often change the balance obtained in the factory. Such changes might be due to temperature, speed, loading, or attaching of heavy couplings to the shaft. It is good practice to balance rotors in the factory production line and refine the balance after installation where only very small vibrations are permitted. It should be noted that vibrations below 0.0001 in. displacement are frequently caused by ball or roller bearing vibration and that further refinement of balancing does not result in any improvements. Portable dynamic balancing equipment is manufactured by the Davey Vibroscope Company, by the General Electric Company, and by the Westinghouse Electric Corporation. A portable machine for balancing of automobile wheels is made by the Stewart Warner Company.

BALANCING OF SPECIAL JOBS. Small Rigid Rotors. The following method of balancing small rigid rotors gives good results, with a minimum of apparatus, and is well applied where frequent balancing operations are not required. The rotor *R*, Fig. 11, is placed in a light wood frame *F*, resting in half bearings in the frame, and driven by motor *M* through belt *L*, whose tension is adjusted by screw *S*. The rotor is first pivoted in plane *C*, the pivots in plane *D* being withdrawn. A spring, not shown, is placed under the frame at bearing *B*, of sufficient stiffness to cause resonance at 700 to 800 rpm. The rotor being driven through the resonant frequency, the deflection indicator *E* is adjusted with its button resting on top of the frame to register vibration. The arc through which the needle oscillates approximately measures unbalanced moment about fulcrum in plane *C*.

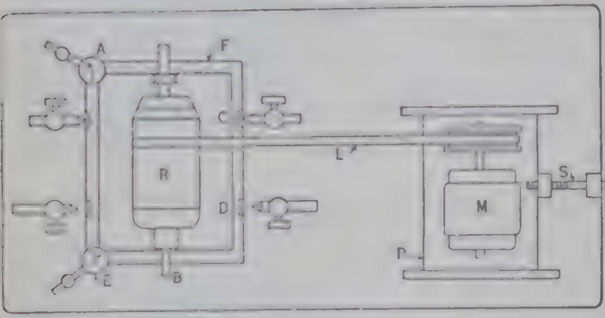

FIG. 11. Balancing set.

To find amount and position of the weight, vibration amplitude is read and a small trial weight is placed successively in four positions 90 degrees apart in plane *D*; the amplitude of vibration is read in each case. A curve of rise and fall of amplitude is plotted against angular position of trial weight, from which amount and position of weight can be estimated. Inspection of the curve shows position where weight subtracts most from the unbalance and adds most to it; the former is the correct position of balance weight. Its amount is estimated by comparing change of vibration amplitude produced by the weight in different positions with the original vibration amplitude, assuming vibration amplitude to be a direct measure of weight required. The trial weight for small rotors may be a piece of wax.

Besides having a light frame to insure large amplitudes, the outfit must not vibrate as a whole because its foundation is insecure. It must be placed where no floor vibrations are transmitted to it; if not, indicator readings will be inconsistent. Furthermore, the frame must be sufficiently stiff to resist all tendency to flexure. A good way to isolate the apparatus from such vibrations and prevent detrimental shaking is to place the outfit on a massive iron plate resting on commercially available vibration mounts or on an inflated automobile inner tube. The driving motor must be well balanced, and a light belt should be used to give a constant tension perpendicular to the oscillatory motion of the frame; the pull should not be too great. To balance the other end of the rotor, the process is repeated, with the other fulcrum. Weights so determined should produce complete balance so that the indicators show no oscillatory motion. This method can be refined by replacing the dial indicator with one of the more sensitive vibration-measuring instruments.

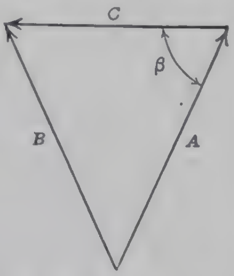

FIG. 12. Vectors representing unbalance.

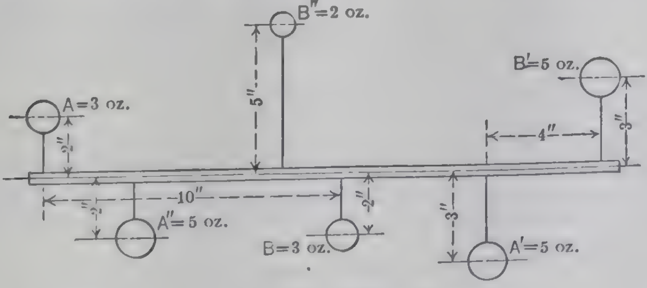
Large rigid rotors are balanced mostly by portable equipment. They work on the principle that the bearing vibration is picked up by electrical vibration detectors whose generated voltage is proportional to the amount of the unbalance, and whose electrical phase angle corresponds to the angular position of the unbalance. The change in the generated voltage and in the electrical phase angle is measured when a trial weight is placed in the balancing plane of the rotor. The voltages, amplitudes, and phase can be represented by vectors as shown in Fig. 12 where vector A represents the output due to the unbalance and vector B the output after the trial weight has been attached. The vector C is then the effect of the trial weight. Balance is achieved when the vector C is equal and opposite in direction to vector A. This can be achieved by rotating the trial weight through the angle β and by increasing its weight in the ratio of A. (See Ref. 5.)

Airplane propeller unbalance may be made up of unbalanced air reaction and mass unbalance. If one blade exerts slightly greater traction on the air than the other, an unbalanced couple is present which revolves with the propeller, always tending to deflect the forward end of the propeller shaft toward the blade exerting the smaller traction, thus causing the engine to wobble. Since traction on one propeller blade is several hundred pounds, any dissymmetry between blades, either of shape or pitch, produces a relatively large unbalanced couple, and aerodynamic unbalance may far exceed pure mechanical unbalance. Hence extremely precise mass balance of airplane propellers may be disappointing. The slightest change in pitch of a blade noticeably affects plane vibration. The problem is complicated by blade deflections during operation which must react on the traction. Propellers of high-power planes are subject to severe engine torque pulsations with resulting vibration, but the exciting force comes from the engine. (See Ref. 6 for a detailed study of this problem.)

Reciprocating Engine Balance. Vibration of reciprocating engines is due not only to unbalanced inertia forces but also to gas pressure forces. The analysis of the inertia unbalance is more complex than for rotors, since reciprocating as well as rotating masses are present, and since vibrations of twice running speed frequency are caused by the second harmonic component of the piston acceleration. The rotating masses can be completely balanced, but not so the reciprocating masses; hence the horizontal forces can be made zero, but the vertical unbalanced forces exist. These unbalanced forces and resulting moments can be made to cancel each other in multicylinder engines. Care should be taken that cancellation is obtained for the forces of the running speed frequency as well as of the second harmonic frequency. A single-cylinder engine is inherently unbalanced, a two-cylinder engine with 180 degree crank angle has unbalanced forces of second harmonic frequency, and a longitudinal rotating moment of running frequency. Four-cylinder engines of 0, 90, 270, 180 degree crankshaft have unbalanced moments of running frequency; for 0, 180, 180, 0 degree crankshaft the forces and moments of second harmonic frequency are unbalanced. Six (0, 120, 240, 240, 120, 0 degree) and eight (0, 180, 90, 270, 270, 90, 180, 0 degree) cylinder engines have all forces and moments balanced. (See Ref. 3, pp. 213 ff.)

RULES FOR DESIGN. A good rule for design of rotating apparatus with moving parts, where unbalanced forces are present, is to keep the center of gravity of the complete moving system as nearly as possible on the rotation axis for all positions of the shaft as it revolves. Next, estimate as nearly as possible the centrifugal couple which remains (weights B and C, Fig. 10) and place anywhere on the shaft a pair of weights to produce a counteracting couple. Figure 13 shows two possible ways of balancing a centrifugal couple produced by weights A and B in one plane, namely, by A', B' or by A'', B''. Note that the pair of weights may be placed anywhere in this plane along the shaft if the couple produced is equal and opposite in magnitude to that of the original weights. The couple in each case is measured by the product of either one of the two weights times its distance



Unbalanced couple $= 3 \times 2 \times 10 = 60$ oz-in.^{2}
I. Balancing couple $= 5 \times 3 \times 4 = 60$ oz-in.^{2}
II. Balancing couple $= 2 \times 5 \times 6 = 60$ oz-in.^{2}, or $5 \times 2 \times 6 = 60$ oz-in.^{2}

FIG. 13. Methods of balancing centrifugal couple.

from the shaft times its distance along the shaft to the second weight of the pair. The two weights do not have to be equal, but the products (magnitude of a weight times distance to shaft axis) must be equal. The use of unequal weights and axial distances is shown where the pair A'' and B'' are counterweights.

WORKMANSHIP. In symmetrical rotors with perfect workmanship and materials, there should be no unbalance. For a ½-hp, 1800-rpm motor, for example, an unbalanced weight of 0.05 oz will produce appreciable vibration of, say, 2 mils amplitude. So small an unbalance cannot be avoided by ordinary shop processes, even with the best supervision. It is cheaper to manufacture rapidly and to balance later.

MEASUREMENT OF AMOUNT OF UNBALANCE. It is sometimes necessary to form a quick estimate of the amount of unbalance in a machine. To measure this in an electric motor, place the motor on rubber pads which should compress at least ⅛ in. under the motor at usual speeds. Maximum vibration amplitude in a direction transverse to shaft is an approximate measure of the amount of unbalance. This is best determined by one of the vibration-measuring instruments.

Another form of suspension used by the author to estimate unbalance is to hang the motor by a relatively long spring through straps or a light cradle, preferably of wood, to reduce inertia. Weight of the motor should stretch the spring perceptibly. Vibration amplitude is measured as before by vibration indicator or meter. This method offers less restraint to the vibrating body than mounting on rubber pads.

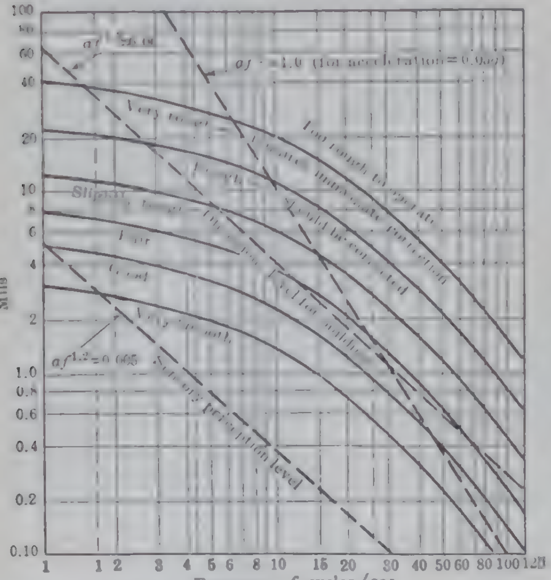


Fig. 14. Machinery vibration tolerance chart. (Reproduced by permission from Vibration Tolerance, by T. C. Rathbone, *Power Plant Engineering*, Nov. 1939)

The object of this test is to find how unbalanced apparatus vibrates when unrestrained by outside forces. The exciting stimulus acts almost entirely against the inertia of the body itself, and oscillations produced are proportional in amplitude to the exciting force. By these methods it is possible to select the best balanced among a number of similar motors quickly, if means for balancing are not available.

Figure 14 is a chart showing vibration tolerance during operation (not special suspension). (See Ref. 7.)

In single-phase motors, there may be a vibration of considerable intensity due to a torque pulsation of twice the a-c frequency, i.e., 120 cps for a 60-cycle circuit (see Ref. 8). This frequency is much higher than ordinary rotation speeds, and thus much higher than vibration from unbalance which is always in step with rpm frequency. It shows up well with the foregoing suspensions; it is easily separated because of its higher frequency and its causing the motor to oscillate about the shaft as a stationary axis. Mechanical balance will not cure this electrical vibration.

Most motor hums from electrical causes are eliminated by elastic suspension. See Article 6.

Gas turbines vibrate in their test stand with a large number of frequencies. Some of them equal running speed, some of them equal the natural frequency of the mounting, and some of them equal wheel frequencies. To determine the unbalance, the vibration of running frequency only should be measured. The General Electric Company manufactures a vibration meter whose frequency range is restricted to the running-speed range. Other electrical vibration measuring instruments can be used in conjunction with electric band pass filters.

ELIMINATION OF SELF-INDUCED VIBRATIONS. A troublesome type of vibration that occurs in rotating machinery operating above the critical speed is self-induced vibration. Its frequency is always the same as the critical-speed frequency, which may be lower than the rpm frequency of the shaft in the same way that the revolution frequency of the earth around the sun is much lower than its rotation frequency about its axis.

Whirling Due to Oil Action in Journal Bearings. This type of self-induced vibration arises only when the rotation of the machine is more than approximately 1.7 the critical-speed frequency. It is produced by wedges of oil driving the journal around in the bearing and exciting a whirl. If a well-balanced machine tends to unstable operation, and vibration appears when the rotation frequency is more than 1.7 the critical speed, this kind of whirl is the probable cause. The best method of elimination is to insure that the critical-speed frequency is more than 60% the rpm frequency of the shaft. Another remedy, in smaller rotors, is to replace journal bearings by ball bearings.

Whirling Due to Frictional Action within the Rotor. Any rotor with self-contained friction produced by flexure while revolving will build up a whirl at any rotational speed higher than the critical. Friction of this type may be produced by rings so shrunk on a shaft that working may occur between the bore of the rings and the surface of the shaft. Frictional working also can arise in laminated structures, carried by the shaft; the structures flex and rotate at the same time.

These phenomena usually occur in motors with flexible shafts that operate far above the critical speed, and in such devices as extractor-type washing machines, which contain rotating parts operating well above the lower critical speed.

Wing Flutter. This phenomenon occurs when vibration of the wing is started by exterior forces such as shock loading, and when energy is added to the system during the vibration (positive damping). In subsonic range flutter can appear when the wing vibrates simultaneously in a twisting as well as an up and down mode. Flutter can be overcome by increasing the natural frequency of one of the modes, or by shifting the elastic axis fore or aft. (See *NACA Report* 496, 1935, by Theodore Theodorsen.)

5. VIBRATION ELIMINATION THROUGH TUNING

SHAFT WHIRLING. Critical Speeds. When a shaft or rotor, revolving in bearings, speeds up to where centrifugal force tending to whip it sideways just balances the elastic stiffness tending to keep it straight, the slightest mechanical unbalance builds up a whirling motion, which may be of destructive amplitude. The rotor then is revolving at a *critical speed*. It is inadvisable to run any rotor or shaft at or near critical speed for any length of time, regardless of perfection of balance. Critical speeds usually are avoided by designing the rotor shaft sufficiently stiff to hold its operating speed well below its critical speed. This sometimes is impossible for very heavy or very high speed rotors of long span between bearings. The shaft then is made sufficiently flexible to insure operation well above critical speed. This practice is to be avoided if possible, as vibration may develop from other causes in operation above critical speeds, although, so far as unbalance is concerned, operation is stable except close to critical speed.

Critical-speed Calculation. Critical speeds of a rotor are almost identical with natural vibration frequencies which the stationary rotor may assume.

Uniform Shaft. The first critical speed is given by the equation

$$f = 7.7(d/l^2)\sqrt{E/w_1} \tag{8}$$

where f = critical frequency, cycles per second; d = shaft diameter, inches; l = span between bearings, inches; E = modulus of elasticity shaft material, psi; w_1 = weight of 1 cu in. of shaft material, pounds. This formula is given in Table 1 (p. 9-03) for a circular bar vibrating between two end supports. For steel, the formula becomes

$$f = 79{,}000\,\frac{d}{l^2} \tag{9}$$

At the first critical speed, the shaft whirls in one loop with nodes at the bearings; at the second critical speed, in two loops with a node in the middle, at four times the first speed; at the third critical speed, in three loops at nine times the first critical speed, etc. Upper critical speeds, which enter only in high-speed installations, are special problems in themselves.

Shafts with Concentrated Loads. A useful approximate formula derived by Dunkerley from analysis, checked by careful tests on models, for a uniform shaft carrying concentrated loads (Fig. 15) is

$$\frac{1}{f^2} = \frac{1}{f_s^2} + \frac{1}{f_1^2} + \frac{1}{f_2^2}, \ldots \tag{10}$$

where f is critical frequency of the whole system; f_s that of shaft *by itself* as calculated from eq. 8; f_1 that of shaft considered as weightless, with load W_1 by itself, given by the last formula in column 3 of Table 2 (p. 9-04), etc., for the other concentrated loads. It is evident that values for x and y in the latter formula depend on location of W_1, W_2, etc., on the shaft. Quantities are inches, pounds, and seconds. This formula should not be used for three-bearing sets.

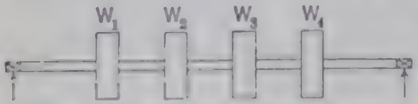

FIG. 15. Shaft with concentrated loads.

Shaft of Varying Cross Section and Load. When cross section of shaft is not uniform, and the load is distributed along it, as in most rotors, the problem is not so simple. It can be solved approximately from knowledge of the static load-deflection curve, as vibration frequency calculated on the basis of this deflection curve is only slightly higher than that based on the true deflection curve for actual vibration.

When static deflection curve is known, vibration frequency or critical-speed frequency is calculated easily from

$$f = 3.13 \sqrt{\frac{W_1y_1 + W_2y_2 + W_3y_3 + \cdots}{W_1y_1^2 + W_2y_2^2 + W_3y_3^2 + \cdots}} \tag{11}$$

where shaft and rotor are divided into a series of slices of convenient length of weight W_1, W_2, etc. (including loads), and corresponding deflections y_1, y_2, etc. (See Fig. 16.) All quantities are inches, pounds, and seconds. The problem is primarily one of static deflection-curve determination, which, in cases similar to Fig. 16, requires using graphical statics. For the solution of such a problem, see Ref. 2.

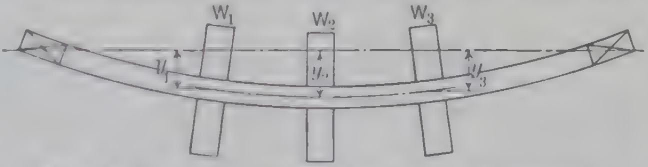

FIG. 16. Transverse vibration of multimass shaft system.

Three-bearing Sets. A three-bearing problem can be solved by eq. 11. Both first and second critical speeds should be found, as they may lie not far apart, whereas the second critical speed of a rotor with only one span will be at least twice the first. At the first critical speed of a three-bearing set, one span deflects upward when the other deflects downward; in finding static deflection curve, loads on one span must be taken as acting upward. Deflection of one span influences that of the other through a bending moment across the middle bearing. The deflection-curve determination must take account of this. The second critical speed occurs at a somewhat higher frequency where both spans deflect in the same direction, with a point of inflection in the shaft near the middle bearing. The static deflection curve then is found from loads acting in one direction, but, again, bending moment is transmitted across the middle bearing. The best procedure for this special problem is to refer to more advanced treatments noted in preceding paragraph.

Bearing Elasticity. All critical speeds are actually somewhat lower than calculation indicates, as no bearing is perfectly rigid. Also, up-and-down stiffness of a bearing is likely to be much greater than its sidewise stiffness. Because of this likelihood, two critical speeds may be present. One involves an elliptical whirl where the motion is mostly up and down; the other, at a speed a few per cent lower, a sidewise, elliptical motion. The lower frequency results from greater sideways elastic yielding of the bearings. For shafts of high natural frequency, critical speed may be 50% lower than calculated for rigid bearings since static deflection of bearing may be comparable to static deflection of shaft.

Elliptical Shafts. If a shaft is not circular, but elliptical or flattened on opposite sides, being stiffer in one axial plane than in one 90 degrees away, bad performance must be expected in operation near critical speed or half critical speed. The rotor evidently will vibrate in one plane at a somewhat lower frequency than in the plane for which it is stiffer. Ideally, with no damping, operation is unstable between these two frequencies. A model shaft and flywheel, with the shaft flattened on two sides, vibrates violently near the critical speed, and must be restricted by a guard ring. Rotors that perform badly near the critical speed are open to suspicion of being built stiffer in one plane than in another. An analysis is given in Ref. 3, p. 408.

TORSIONAL VIBRATION OF LOADED SHAFTS. Critical torsional vibration frequencies as well as transverse criticals may occur in shafts carrying flywheels and subject to periodic torque impulses, such as occur in Diesel engines. Torsional critical speeds are more insidious than transverse, as they are not always evidenced in operation by excessive vibration, as are the transverse criticals. Since dissipation is small, operation on a torsional critical speed causes large torsional stresses which often result in fatigue failure.

In ship's drives torsional vibrations lead often to tooth separation of the gears when the oscillating torque is larger than the driving torque. This separation will cause impacts on the teeth of the gears, making replacements necessary after short periods of operation.

Loaded shafts only are treated below. Torsional inertia of shaft itself is neglected, as it usually is small. It cannot be neglected in all cases, but in many problems nearly all torsional inertia is concentrated in certain planes, as in shafts carrying flywheels and crankshafts. See Refs. 9 and 10.

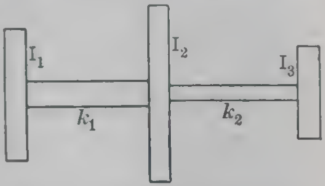

Fig. 17. Shaft carrying three flywheels.

Shaft Carrying Three Flywheels. Figure 17 shows a shaft carrying three flywheels, one of which may be the equivalent of a crankshaft. This system has two critical frequencies, given by the expression.

$$f = 3.13\sqrt{\frac{-B \pm \sqrt{(B^2 - 4AC)}}{2A}} \tag{12}$$

where $A = (I_1I_2I_3)/(k_1k_2)$; $B = -[\{(I_1I_2 + I_1I_3)/k_1\} + \{(I_2I_3 + I_1I_3)/k_2\}]$; $C = I_1 + I_2 + I_3$; I_1, I_2, I_3 = moments of inertia of the three flywheels; and k_1, k_2 = torsional elastic constants of the two shaft lengths between the flywheels, inch-pounds per radian of twist.

For a disk-shaped flywheel of weight W pounds and radius r inches,

$$I = \frac{Wr^2}{2} \text{ pound-inches}^2 \tag{13}$$

If the shafting that spans distance between two flywheels is of uniform diameter for a given span,

$$K = \frac{\pi N a^4}{2L} \tag{14}$$

where N = rigidity or shear modulus of shaft material; a = shaft radius, inches and L = length of span, inches. The lower of the two frequencies given by eq. 12 is that for which the inside radical is negative. The first and last flywheels vibrate in opposite phase with a node somewhere between. If the system is made up of three identical flywheels connected by two identical spans the node is exactly at the middle flywheel, which remains stationary while the two end ones vibrate against each other. For the upper of the two frequencies, the end flywheels vibrate in phase; the middle one is in phase opposition, with a node somewhere along each connecting shaft length, making two nodes in all. No more resonant frequencies are possible with this system.

Shaft with one flywheel at each end is solved by eqs. 12, 13, and 14, where $I_2 = 0$, in which case eq. 12 reduces to the simple form

$$f = 3.13\sqrt{\frac{(I_1 + I_3)k}{I_1I_3}} \tag{15}$$

where $k = k_1k_2/(k_1 + k_2)$. This system contains one resonant frequency. Torsional elastic constants k_1 and k_2 are calculated by eq. 14 for shaft sections of uniform diameter as before, where L_1 and L_2 are lengths of the two shaft sections, and all quantities are in inch-pound-second systems. If the shaft is of uniform diameter from I_1 to I_3, the constant k can be found directly by eq. 14.

Design Considerations. The torsional stiffness of shaft and inertia loads must be such that none of the calculated natural frequencies is in step with any periodic impulse from the driving engine. The torque impulses from an engine may be of the order of $1/2$, 1, $1\,1/2$, 2, $2\,1/2$, 3 etc., i.e., the lowest frequency impulse is one-half the running speed frequency. For airplane engines and for ship drives the propeller-blade frequency is one of the stimulating frequencies, and often the one which causes the largest stresses in the shaft. It is desirable, but often not practical, to make the system so stiff that all its critical frequencies are above the highest torsional impulse frequency. Friction devices sometimes are used for smaller engines, whereby one or more inertia parts are permitted to turn on the shaft against friction clamps. When torsional oscillations develop, the clamps damp them out. Friction devices of this kind often give trouble.

Most actual cases cannot be treated by the simple analysis given above because of varying shaft sections or the presence of more than three inertia parts, etc. For more complicated problems in this field, as those on automobile crankshaft design, see Ref. 2;

Ref. 3, p. 232; and Ref. 11. An understanding of general principles, however, should enable a designer to approach problems of this kind intelligently and to guard against torsional vibration.

TURBINE-WHEEL VIBRATION. Cause. The edge or periphery of an elastic disk will transmit a train of flexural waves around it at a characteristic speed determined by mass per unit area and stiffness of the disk. As the boundary of the disk has a finite circumferential length, the wavelengths must have certain fixed values; e.g., the disk edge may carry a continuous train of 2, 4, 6, or 8, etc., waves, whose wavelength is 1/2, 1/4, 1/6, 1/8, etc., of the disk circumference. Each wave train has a different velocity, longer wavelengths moving at considerably higher speeds than shorter. In a disk of uniform thickness, supported at the center, wave speed, revolutions per second, can be calculated by

$$\text{Revolutions per second} = K(h/r^2)\,\frac{\sqrt{Eg/W_1}}{2n} \tag{16}$$

where K depends on n, the number of nodal points along the disk edge. For values of K and meaning of symbols, see p. 9-04.

Turbine wheels are not of uniform thickness and must be calculated by special methods. For detailed discussion of turbine-wheel vibration and design, see Ref. 12.

Critical speeds exist for turbine wheels at which operation is hazardous. These critical speeds are equal to the several wave-train speeds given by eq. 16 except for a correction necessary to allow for stiffening effect of centrifugal force, which makes wave speeds for a revolving wheel somewhat higher than those given by eq. 16 for a stationary wheel. See Ref. 12.

When a turbine wheel runs at one of its criticals, the wave train at whose speed the wheel revolves will be stationary in space, because the wave train moves backward in the wheel at the same speed that the wheel turns forward. A small axial pressure on the wave zone of the wheel near its outer edge, i.e., on the bucket zone, may sustain and build up such a standing wave train. Thus only the wave train moving backward in the wheel is built up, but the corresponding forward-moving wave train is not maintained.

Long waves, corresponding to 4 or 6 radial nodes, build up more easily than wave trains of shorter wavelength. Large, relatively thin wheels are more susceptible to wave-building action because of the greater area on which steam acts and their greater flexibility, permitting small initial disturbances from which wave trains build up to be more easily excited. For the same reason large-amplitude waves build up easily, with resulting fatigue failures of disk material.

Higher radial modes can be dangerous although their amplitudes are relatively small. The distance along the periphery between the nodal diameters is rather small, and then small amplitudes cause considerable stresses in the wheel. Failures near the bucket roots are known to have occurred in high-speed wheels for high-pressure turbines for vibrations with as many as 80 nodal diameters, at frequencies in the thousands of cycles per second.

Prevention. The remedy is twofold. (1) Design the wheels to avoid operation at all critical speeds or wave-train speeds. For small turbines, this usually can be done; for large wheels, it is not practical for the highest-speed wave train, unless the wheels are excessively heavy. The next best remedy is to place operating speed halfway between those of two consecutive-node wave trains. (2) Do not depend too much on avoiding critical speeds, but keep the buckets and wheels sufficiently stiff, based on past successful operation.

Precautions. It is not safe to depend on calculation alone. Measured frequencies, from which critical speeds can be calculated, may diverge 10% from the best calculations, because of initial stresses in the disk itself or to cramping of buckets. A hoop tension or compression along the outer zone of the disk will alter frequency materially. For details see Ref. 12.

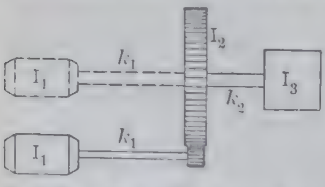

FIG. 18. Torsional oscillation in gear train.

GEAR-WHEEL VIBRATIONS. Torsional Oscillations in Gear Trains. Figure 18 illustrates a system of gears and flywheels subject to torsional oscillation. The two frequencies of this system are best calculated by reducing to a system equivalent to Fig. 17, by replacing I_1 and K_1 (Fig. 17) by I_1' and K_1', where $I_1' = n^2I_1$ and $K_1' = n^2K_1$, n being gear ratio. The inertia of the pinion has been neglected. If moment of inertia, I_2, of the gear wheel is small compared with I_1 and I_3 of the flywheels, I_2 may be taken as zero. There then is but one resonant frequency, found by

$$f = \sqrt{\left(\frac{I_1' + I_3}{I_1'I_3}\right)\left(\frac{K_1'K_2}{K_1' + K_2}\right)} \tag{17}$$

It is remarkable that in this case the pair of gears gives the same frequency that would obtain if the shafts were fixed end to end with no gears between, regardless of value of gear ratio n. This statement can be checked by substituting $I = I'/n^2$ and $K = K'/n^2$ in eq. 17, and comparing with result obtained when I' and K' are used. The relative vibration *amplitudes*, however, depend directly on n; that is, in Fig. 18, when gear train is present for a given oscillation amplitude of I_3, that of I_1 is $1/n$ times its value for the shafts directly connected without the intermediate gears. For more than one pair of gears the problem is more complex. See Ref. 2, p. 256, for a mathematical analysis of this problem.

Vibration of Gears Due to Impact. Practically all gears produce a hum of gear-tooth frequency, which in high-speed gearing under load may be very penetrating. This is primarily a forced vibration, and will be little helped by tuning. The only sure cure is precision of manufacture, together with a design which permits perfectly constant angular velocity for all tooth positions. Sometimes a resonant ring in gear wheels also is present. This type of noise can be largely eliminated by methods given under the heading of vibration damping (see Article 7).

VIBRATION OF STRUCTURES. All structures and buildings are subject to resonant vibrations of several frequencies; the lower frequencies arise from a swinging of the whole structure; the higher from vibrations of component parts. The best way to eliminate such vibrations, when set up by a periodic force of known frequency, is by some method of tuning.

FOUNDATION VIBRATIONS OF MACHINERY. Foundations of heavy machinery may be structures of considerable size. Sidewise and up-and-down frequencies in a steam turbine should be roughly estimated in design and compared with the revolution frequency or, for other types of machinery, with the predominant exciting frequency. Accurate calculations of frequencies of such structures are too complex to be worth while unless a thorough study is contemplated. Rough estimates based on common-sense application of vibration principles give almost as reliable results as more refined calculations.

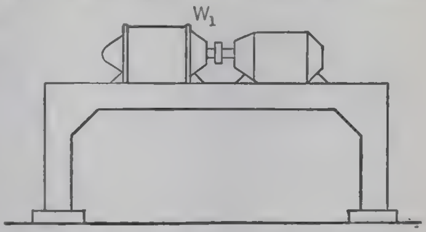

FIG. 19. Structure supporting rotating machinery.

Procedure. Reduce the system to a single lumped mass vibrating against single stiffness constants, one for up-and-down motion, one for sidewise motion, etc., and use eq. 3. For example, a structure (Fig. 19) carries rotating machinery of weight W_1. The total weight used to calculate up-and-down vibration frequency includes, say, half the structure floor, as only the middle portions vibrate up and down to any extent. For sidewise vibration, the total floor weight and part of the columns is included, as the whole floor and column tops move through approximately full amplitude. Constant k is found in each case by estimating the downward force on the platform and the sidewise force, respectively, in pounds required to produce 1 in. of deflection. This estimate requires some ingenuity, but with a little practice it is not difficult to obtain an approximate result. Frequency depends on the square root of mass and stiffness, and error is minimized in the final result.

Even if the principal modes of vibration have frequencies a safe distance from the operating frequencies, individual parts of the structure may resonate, especially when built of steel members. To cure resonance of individual members, stiffen or load them in different ways until vibration disappears. This cure usually is not difficult. It evidently is impractical to attempt to predetermine frequencies of *all* the individual members of such a structure.

BUILDING VIBRATIONS. Ordinary buildings have sidewise natural frequencies of 2 or 3 per sec, as is clearly shown during slight earthquakes, or when delicate apparatus is being mounted.

GROUND VIBRATIONS. Heavy machinery causes local vibration of its foundation, and also at times earth waves radiating in all directions to a considerable distance. If the foundation rests on bedrock, such transmission is negligible; with a foundation on clay or sand, and a periodic force of high intensity and low frequency, surface waves can be detected 1/2 mile or more away in clay or sand beds. Ground waves may be avoided by placing heavy machinery foundations on bedrock and by avoiding clay or sand flats, as well as unbalanced exciting forces. Bedrock, however, transmits objectionable sound vibrations of higher frequency better than clay.

RESONANCE IN HELICAL SPRINGS. Helical springs subject to periodic compression and extension, as automobile valve springs, may resonate badly, with result-fatigue failures. Longitudinal resonant frequencies in helical springs fixed at each end are calculated with considerable precision by

$$f = (n/2l)\sqrt{kg/w} = (9.8n/l)\sqrt{k/w} \tag{18}$$

where n = number of half waves between fixed ends; l = length of spring, inches; w = weight per inch of axial length, pounds; k = elastic constant of spring *per unit length*, i.e., force, pounds, necessary to double the length of spring; and f = cycles per second. Thus, the lowest frequency, where $n = 1$, corresponds to one-half wave between ends; the next, where $n = 2$, to two half waves, etc. (See Fig. 20.) To avoid these resonances, the spring must be designed so that none of these frequencies is in the operating range. If possible, its stiffness should be such that the lowest resonant frequency for which $n = 1$ is above the operating range of frequencies.

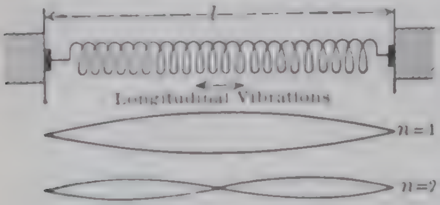

FIG. 20. Vibration of helical spring.

SHIP VIBRATION. Hulls of ships, particularly steel ships, are subject to resonant vibrations. A long ship has several resonant frequencies in which flexural vibrations of the ship as a whole occur, with two or more transverse nodal lines. These frequencies can be calculated approximately and should not be in step with exciting forces. The principal periodic exciting force to be avoided is propeller blade frequency, i.e., revolutions per second times the number of blades. This force comes from a periodic reaction of water from the propeller on parts of the stern, which is difficult to eliminate completely. Such a condition of resonance may be tuned out to a large extent by altering cargo distribution, thus altering natural frequency

DYNAMIC VIBRATION ABSORBER. Force elimination, or change of mass and spring constant to avoid resonant frequency vibration, is not always possible, especially when the vibrating force varies over a wide frequency range. The dynamic vibration absorber might then find application. It consists of a small spring-mass system attached to the machine (large spring-mass system) and tuned to the disturbing frequency (see Fig. 21). The amplitude of vibration of the machine under a vibrating force of its original resonant frequency is then exceedingly small; however, two new resonant frequencies occur whose frequencies are a function of the mass ratios and frequency. When a damping member is paralleled to the spring of the small mass-spring system, the maximum amplitude of the big mass which is obtained for excitation over the complete frequency range is $\epsilon = \sqrt{1 + (2/\mu)}$ for the optimum condition where the tuning f_m of the absorber is $f_m = 1/(1 + \mu)$. μ is the ratio of the absorber mass to the mass of the machine, ϵ is the ratio of the main mass deflection to the base deflection, and f_m is the ratio of the natural frequency of the absorber system to the main system.

Dynamic vibratory absorber with damping

FIG. 21. Idealized dynamic vibration absorber.

Internal-combustion Engines. Dynamic vibration absorbers are being used to reduce torsional oscillations. Instead of small spring-mass system, a pendulum is used. The natural frequency of the pendulum is directly proportional to the rotational speed of the shaft when centrifugal forces are acting on the pendulum mass. By proper design the pendulum has a natural frequency which is always equal to rotational frequency or its multiples. For details of these centrifugal pendulums, see Ref. 3, p. 274.

Ship Stabilizers. The Frahm tank installed in ships to reduce rolling works on the principle of the dynamic vibration absorber. The idealized Frahm tank consists of a U-tube filled with water. The water level oscillates when the U-tube is vibrated. Damping is realized by installation of throttles at the openings of the tubes. See Ref. 3, p. 136. Similar effects are obtained with a gyro stabilizer, which is a large gyroscope coupled to the ship by suitable damping.

6. VIBRATION REDUCTION BY ISOLATION

Forced vibrations may be cured by resorting to isolation; they do not yield readily to damping and cannot be tuned out. The standard method of isolation is to use an elastic suspension.

ELASTIC SUSPENSIONS function through ability to reduce the periodic force reaction of a vibrating body on its support. Figure 22 shows the simplest possible spring suspension, where a weight W, with an up-and-down forced vibration of frequency f imposed on it, is supported by a vertical spring. Transmissibility of such a spring support is given by

$$\text{Transmissibility} = \epsilon = \frac{f_0^2}{f^2 - f_0^2} \qquad (19)$$

where f_0 is natural or resonant up-and-down frequency of spring support as given by eqs. 3 and 5. Transmissibility may be defined as the ratio of vibration forces actually transmitted to those which would be transmitted without spring suspension. Thus, to be of use, ϵ must be less than unity; experience shows that in most cases to be really effective ϵ should be as small as one-thirtieth to one-fortieth. This means that f_0 should be $^1/_5 f$ to $^1/_6 f$. Figure 23 shows a graph of eq. 19 as a function of $f/f_0 = r$.

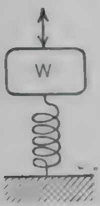

FIG. 22. Simple elastic suspension.

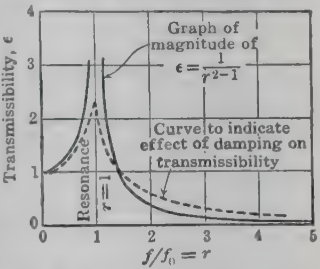

FIG. 23. Transmissibility with (dotted curve) and without (solid curve) damping.

PRECAUTIONS IN USE OF ELASTIC SUSPENSIONS. All elastic suspensions necessarily have their own resonances. Thus if a suspension is designed to isolate a frequency of f = 120 cps with a resonant frequency f_0 = 30 cps, no 30-cycle exciting frequency must be present in addition to the 120-cycle one. This is especially true for rotating machinery, whose rotation speed is usually in that field. Figure 23 shows that transmissibility is greater than unity when f approaches f_0, and may be very large near resonance. Furthermore, ϵ is always greater than unity when f is less than f_0. Nearly all elastic suspensions have resonance frequencies other than f_0 corresponding to the particular mode of vibration for which they are designed. This fact must be considered in design.

Elastic suspensions do not damp a vibration by friction, but prevent transmission by power to isolate. Contrary to general belief, damping increases transmissibility, although the increase is small with a moderate amount of damping. (See Ref. 4, pp. 96 107.) A moderate amount of damping is of advantage as it safeguards against excessive vibration near resonance, but not because it improves isolation. Resonant frequency of the suspension is excited when the machine is started or stopped, or in case of shock excitation, as for punch presses. Elastic suspensions for punch presses should have a considerable amount of damping. See eq. 5 for frequency calculation from gravity deflection d.

ELASTIC SUSPENSION MATERIALS. Steel, rubber, and cork are commonly used for spring suspensions.

Steel has the advantage of being very durable. It contains practically no damping, and therefore is subject to possible resonances. It has also the disadvantage that very high frequencies are transmitted through the steel mounting in the longitudinal direction just as a listening rod held against a motor bearing transmits the high frequency bearing noises even though its transverse natural frequency is very low. It is good practice to place rubber pads in series with the steel suspension when frequencies above 200 cps are present. These rubber pads can be rather stiff since they have to isolate only the higher frequency components.

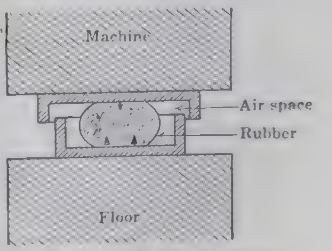

FIG. 24. Rubber support.

Rubber is more flexible than steel from the design standpoint. It has some damping. To avoid age hardening, only the highest grade, produced for this special purpose, should be used. Long life is then possible, even under severe conditions. Rubber should not be loaded more heavily than 80 psi. It is highly incompressible and yields almost entirely through shear. In designing rubber supports, space for elastic flow must be maintained, or they may be too rigid (see Fig. 24). Rubber pads usually should be of small area so that they can freely squeeze out sideways under load. For a given thickness the hardness of a rubber pad increases disproportionately under compression with increase of area (see Fig. 25).

Rubber must not be used at temperatures over 120 F and below −20 F. When applications beyond this temperature range are required it is necessary to take into account the considerable change in modulus of elasticity. Natural rubber must not come in contact with oil. Coating with oil-resistant varnish affords some protection. Some synthetic rubbers are oil resistant, however, but are frequently inferior because of lower tensile strength, higher damping, greater change of elasticity modulus as function of temperature, and creep. For long-time applications there is some creep in natural rubber mounts. Commercially, rubber mounts are available for the majority of applications, using, almost exclusively, rubber loaded in shear and bonded to metal adapters which can be readily attached to the vibrating structure (see Fig. 26 for typical mounts). Manufacturers of mounts are the Lord Manufacturing Company, Erie, Pa.; MB-Manufacturing Company, New Haven, Conn.; L. N. Barry Company, Cambridge, Mass.; and Vibration Eliminator Company, Long Island City, N. Y.

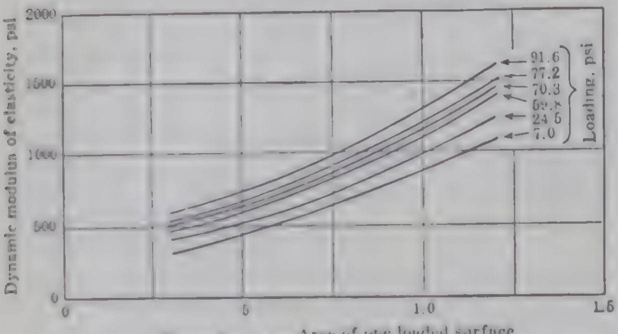

FIG. 25. Modulus of elasticity as a function of shape for various loadings, rubber compression mountings.

Cork differs from rubber in that it is directly compressible, and space for elastic flow is not needed. The stiffness of cork increases directly as its area when used in large pads. Cork pads of comparatively large area thus may be effective in isolation, particularly for higher frequencies in the sound range. Cork has the disadvantage of gradually compressing under load after initial loading, resulting in gradual loss of isolating power for lower frequencies. Despite this fact, cork has performed successfully for many years in some installations. Cork mounts are being superseded today by rubber mounts except for a few special applications. Mounts using cork are available from the Korfund Company and Armstrong Cork Company.

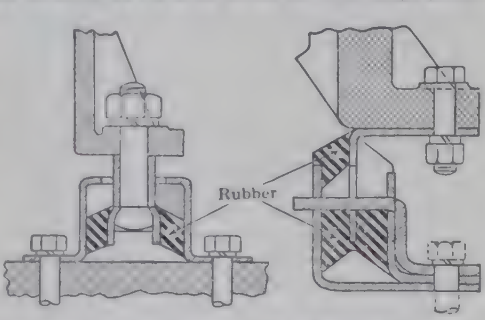

FIG. 26. Shear mountings employing rubber bonded to channel or angle bars.

SUSPENSION FREQUENCY CALCULATIONS for up-and-down frequencies are in all cases made by eq. 5, but for rubber and cork actual frequency is higher than calculated, because of imperfect elasticity. For some materials, gravity compression d must be greater than required by eq. 5. Cork, to obtain required suspension frequency, may be two or three times as great as for perfectly elastic material like steel.

APPLICATIONS. General application of elastic suspensions requires considerable knowledge of vibration. Elastic suspensions usually have several modes of vibration. Exciting frequencies, other than the one being isolated, probably will be present, e.g., revolution frequency of a rotating machine operating over a wide range. A suspension must be designed so that all its vibration frequencies avoid all exciting frequencies. An otherwise good elastic suspension may have an objectionable low-frequency quiver. A suspension, flexible in some directions, often must be rigid against belt pull, in which case rubber is better than steel springs. Steel springs sufficiently flexible in one direction may be too flexible in others. Flexible mountings operating on a floor that is both light and flexible, e.g., spring-suspended machinery on spring-supported car bodies or airplane engines on the relatively light structure have to be determined by analysis of the compound elastic systems with more than one mass and elastic connection.

There is a general tendency to assume that a spring-mounted machine will have only one vertical natural frequency. Since a mounted object will usually have at least six natural frequencies, such a procedure may be embarrassing and dangerous. The following modes of vibration can be expected for a machine supported by elastic mounts at its four corners: (1) Vertical vibration in the vertical plane. (2) Torsional vibration around the vertical axis. (3) A low rocking mode in the vertical plane around a front-rear axis. (4) A high rocking mode in the same plane as 3. (5) A low rocking mode in the vertical plane around a left-side right-side axis. (6) A high rocking mode in the same plane as 5.

If the ratio of the horizontal to vertical spring constant is less than 0.5, the mounts can generally be arranged so that all frequencies are nearly equal or less than the vertical frequency. If possible, the line of action of the mounting should pass through the center of gravity of the mounted equipment, so avoiding coupled vibrations, i.e., a translatory force will excite translatory motion only, a torque or a moment will excite only rotation about one of the axes. (See Ref. 4, pp. 96-107, and Ref. 13.)

FLOOR SUSPENSIONS. Some machinery can be isolated by mounting on a comparatively flexible floor frame, elastically supported on the solid floor below. This prevents the transmission of rumbles, grinding noises, and hums through the building, to radiate sound from panels, etc. Springs or rubber pad suspensions used at intervals of about 1 ft, depending on the floor load, will perform well, steel being more permanent. The flooring should yield perceptibly, say 0.1 in., under machinery load. A difficulty is the presence of possible side swings and low-frequency quivers, which are best cured by rearranging supports, rather than by calculation. Printing-press vibration, for example, has been so isolated. Machinery requiring exact alignment, as an accurate lathe, cannot be placed directly on a flexible floor, but must be set on a rigid, spring-supported platform. Such work is done best by concerns specializing in construction of elastic floorings.

If a cork layer is used instead of a spring-supported flexible floor, low-frequency rumbling noises may be transmitted, if not the higher frequency notes, unless a layer is used that is thick enough to permit appreciable compression ($^1/_{16}$ to $^1/_8$ in.) under load.

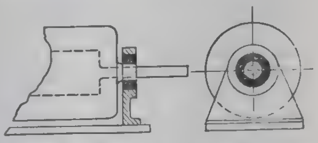

Fig. 27. Elastic motor suspension using rubber.

MOTOR SUSPENSIONS. **Single-phase electric motors** are subject to torque pulsation of twice the a-c supply frequency, i.e., 120 cps for a 60-cycle source, **causing a 120-cycle torsional forced vibration of both stator and rotor about the motor axis. This 120-cycle vibration causes the hum noticed in domestic use of such motors, which a well-designed elastic suspension will completely eliminate. To isolate such 120-cycle vibrations, a suspension of torsion flexibility is required, whose natural frequency** f_0 about the motor axis is, say, 20 cps; since $f = 120$, $f/f_0 = 6$, and, from eq. 19, $\epsilon = 1/35$, giving fair isolation. This support must have considerable transverse rigidity to resist belt pull, and also to prevent resonating to the speed frequency due to slight mechanical unbalance. Figure 27 shows a satisfactory elastic suspension using rubber.

Polyphase electric motors with good elastic suspension can be used instead of d-c motors where noiseless operation is required. Although subject to much less vibration than single-phase, no polyphase motor is free from electrical hums which can be transmitted to surrounding structures. Especially designed elastic bases are furnished by the manufacturer. The design of such a base is not easy, but if correctly designed with rubber pad suspensions, its performance is excellent.

AUTOMOBILE-ENGINE SUSPENSION. Flexible supports of comparatively low resonant frequency are being used on many types of automobile engines with apparent success. Avoidance of suspension resonances is difficult with a wide operating speed range and consequent wide range of exciting frequency. The principal resonant frequency is low and is easily passed through in accelerating the engine. At normal operating speeds, isolation is excellent, and engine vibration is hardly perceptible in the car. The chief disturbance is the variation in torque reaction, and the mountings are applied so as to afford torsional resilience about a longitudinal axis. The axis about which the moment of inertia is least is chosen, and virtual center of gravity suspension is attained.

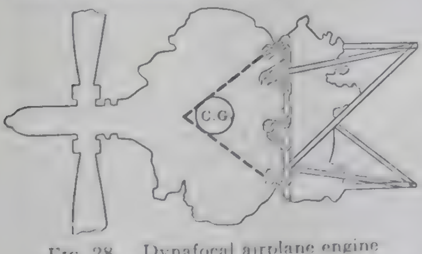

Fig. 28. Dynafocal airplane engine mounting.

AIRPLANE-ENGINE VIBRATION. For in-line engines the same principles as for automobile-engine suspension apply. For radial engines supported from one side only, the Dynafocal system (see Fig. 28) is being used. This system provides center-of-gravity suspension, the individual mountings being inclined so that they point toward a focal point just beyond the center of gravity.

ISOLATION FROM VIBRATION. The isolation of certain bodies from forced vibrations and waves of outside origin sometimes is necessary. This problem is the reciprocal of that of vibration elimination through tuning, and the same principles and formulas apply.

Isolation of delicate apparatus from building tremors requires an idea of the approximate frequencies present, obtained by observing quiver of the surface of a dish of mercury, a Frahm tachometer, or any other vibration instrument permitting recording of the vibration wave shape. Building and ground tremors (from vehicles, etc.) contain low-frequency harmonics which can be isolated only by a suspension having frequency less than 1 cps. This follows from transmissibility eq. 19, where f is frequency of the building tremor and f_0 that of the suspension. Evidently both the up-and-down oscillating frequency and the sidewise swing of the suspension must be very low. The instrument to be isolated should be hung by long springs (helical) which extend several inches under the load. (See eq. 5.) Since a seconds pendulum is about 3 ft long, suspension springs and wires must be at least several feet long to insure a low enough frequency of sidewise swing.

Several pieces of apparatus may be isolated together on a relatively massive platform hung either from the ceiling or a davit, using springs extending several inches under the load.

Good isolation sometimes can be obtained by placing the apparatus on a heavy metal plate resting on an inflated automobile inner tube. This is not sufficient for very low-frequency disturbances, because to screen from the latter the suspension must yield several inches under load.

All helical springs used in suspensions should be loosely stuffed or wrapped with damping material to prevent local spring resonant oscillations. It is important not to use too much damping, as in a spring suspension it increases the transmissibility.

When frequencies above 5 cps are to be isolated, a suspension using rubber pads or commercially available rubber mounts is often cost and space saving.

VEHICLE SUSPENSION. A successful vehicle suspension should be as flexible or of as low frequency as is consistent with stability. It must have some damping. The lower the frequency the better the isolation from road impulses. Damping is essential in vehicle suspensions, to limit unavoidable resonant bounding oscillations due to the great range of exciting frequencies produced by various road conditions and speeds.

In railroad cars, the use of built-up leaf springs provides damping by friction between individual leaves. In automobiles, leaf spring friction is not sufficient. So-called shock absorbers are necessary, whose function is to reduce transmissibility at or near suspension resonance points. For other exciting frequencies, transmissibility is slightly increased by such devices.

Automobile suspensions must isolate against more severe vibration excitation than railroad car suspensions. They are compound, with one elastic support between wheel and road and another between wheel and car body. Figure 29 represents schematically such a system with damping omitted; m_1 represents car body mass; k_1, car spring elastic constant; m_2, wheel mass; k_2, tire elastic constant. Actually the system is more complex, but the scheme of Fig. 29 yields the two principal modes of vibration of ordinary automobile suspensions.

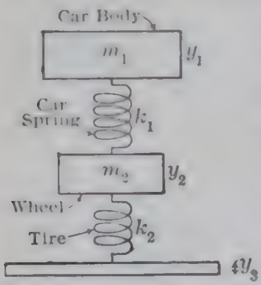

FIG. 29. Schematic representation of vehicle suspension.

Because of its compound character, transmissibility is given by an expression which contains both its resonant frequencies, f_1 and f_2, as well as exciting frequency, f, from the road. Where y_1 and y_3 are amplitudes, this expression is

$$\text{Transmissibility} = \frac{y_1}{y_3} = \frac{1}{[(f^2 - f_1^2)/f_1^2][(f^2 - f_2^2)/f_2^2]} \qquad (20)$$

The higher resonant frequency f_1 is excited by "washboard" roads which cause the wheels to resonate up and down between the road and stops on the vehicle body. This condition arises when $f = f_1$, and without shock absorbers would be excessive. The lower resonance occurs when $f = f_2$, where the whole car body swings up and down in step with long waves in the road. At this frequency shock absorbers act again. This compound system reduces to a simple one, with transmissibility given by eq. 19 when a rigid connection replaces k_1. In this case, f_1 becomes so large compared with f that the first factor $(f^2 - f_1^2)/f_1^2$ can be replaced by unity.

This discussion brings out the principal factors in vehicle suspensions. Frequencies f_1 and f_2 should be as low as possible so that ϵ is as small as consistent with stability between resonant points. At the same time, ϵ is limited at these points by shock absorbers which are not so energy absorbent that ϵ is appreciably increased between resonant points. For derivation of eq. 20, see Ref. 4, pp. 107–109. See also Ref. 14.

SHOCK MOUNTS. Punch presses should be isolated against transmission of impacts into the floor. The exciting force has a multitude of frequency components. It is not practical to mount for the lowest frequency component applying the principles mentioned above, since this would lead to a rather unstable support that would oscillate at its resonant frequency after each impulse with rather large amplitude. A natural frequency of approximately 30 cps has been found suitable for this type of mount. Shock mounts should have a considerable amount of damping. Rubber is used mostly as resilient material.

7. VIBRATION DAMPING

Vibration damping is reduction of vibration by energy absorption such as friction. Neither avoidance of resonance by tuning nor prevention of transmission by spring suspensions are damping processes. Vibration damping is of maximum effect in curing resonant vibrations where the rate of energy supply exciting vibration is relatively small.

SLIDING FRICTION DAMPING exists in built-up leaf springs whose leaves slip against each other, creating friction when the spring oscillates. This friction is important in limiting resonant vibrations of railroad cars on their springs. Sliding friction damping is used in some forms of automobile snubbers.

Torsional oscillations in shafts may be limited by a heavy flywheel, attached to the shaft by sliding friction, which slips against oscillations of the shaft. Critical speed vibrations of shafts can be eliminated by spring-supporting bearings in a collar that permits slipping against a friction clamp. Sliding friction dampers often give trouble from variable friction due to variation of pressure of the clamps, to scoring, or to the presence of foreign materials like oil.

Sliding friction in the joints is important in limiting vibration of steel structures because of the extremely low internal friction of steel. Turbine wheels with separately made buckets have far more resistance to vibration than those with buckets integral with the disk.

IMPACT DAMPING arises from the impact of loose parts of a structure in an effort to vibrate independently. Such impact has a strong dissipating effect and rapidly damps vibration. A steel gear which otherwise would ring under a hammer blow will sound quite dead if a steel ring is snapped into a slot under the rim on each side. Impact damping is effective in dissipating high-frequency vibrations of small amplitude.

FLUID DAMPING differs from sliding friction damping in that the resisting force rapidly increases with the velocity of motion; with sliding friction resisting force is independent of velocity. Dashpots utilizing fluid flow have powerful damping action for large amplitudes; the damping action falls off rapidly with slow motion at small amplitudes.

SOLID DAMPING. All solid materials have more or less internal friction damping resistance to periodic deflection. The most perfect tuning fork loses its vibration amplitude from this cause when all external friction effects, as air resistance, have been removed. Softer elastic materials, as rubber, have considerable internal friction. Steel has so little solid damping that structures built up of steel members owe nearly all their vibration resistance, as a whole, to sliding and impact friction joints. Individual members and panels, however, may be damped largely through what internal friction exists. Individual members in a steel structure may be highly resonant.

Concrete has ten times as much damping as steel, and concrete structures are not particularly resonant. The overall damping in a steel structure does not differ greatly from that of a similar concrete structure, because of dissipation in friction and vibration interference between individual members.

8. METHODS FOR SOLVING VIBRATION PROBLEMS

Calculations of the natural frequencies of coupled systems become rather complex. These problems are often solved by punch cards that are fed through tabulating machines. Such a system is widely used for the calculation of the natural frequencies of shafts supported by several bearings. (See Ref. 15.)

Electromechanical analogies are frequently used where mechanical quantities such as force and velocity are set equivalent to electrical quantities such as voltage and current. (See Ref. 16.) An electrical circuit representing the mechanical constants is often found to be useful. Difficulties in the application of this analogy, however, arise because the damping of the electrical circuit often cannot be made low enough for the analogy. The electromechanical analogy is especially useful when coupled mechanical and electrical systems are to be analyzed, such as servo systems and electromechanical transducers.

Differential analyzers have been found to be very useful for solving problems of torsional vibration. (See Ref. 17.)

NOISE

9. NOISE IN GENERAL

DEFINITION. Noise is defined as an undesirable sound. When vibrations of bodies are transmitted into the air as sound waves of different frequencies, the heterogeneous sound resulting is noise. Noise reduction is important in engineering.

VELOCITY OF SOUND is a wave phenomenon in the atmosphere. It has constant velocity V of transmission, regardless of its frequency or wavelength, of about 1100 ft per sec.

$$V = \sqrt{1.4pg/w} \tag{1}$$

where V = velocity, inches, per second; p = atmospheric pressure, pounds per square inch; g = acceleration of gravity, inch-seconds^{-2} = 386; and w = weight of 1 cu in. of air. Since w varies as p, V is unaltered by pressure change. When temperature increases, however, w alone decreases. Thus while not altered by pressure change, transmission velocity is proportional to the square root of absolute temperature, and varies about 5% in ordinary temperature ranges.

PERCEPTION OF SOUND. The human ear can perceive as tones, noise frequencies from 25 to over 16,000 cps. In its most sensitive range, 500 to 6000 cps, the ear is extraordinarily sensitive, the wave amplitude of easily detected sounds being of molecular dimensions. In this range, amplitudes of a millimeter are heard as terrific noises. Sounds in this range are easily excited and difficult to eliminate.

FREQUENCY AND WAVELENGTH. The frequency of a sound is the number of complete waves transmitted per second. High frequencies correspond to short wavelengths and vice versa.

$$\text{Wavelength} = \lambda = \frac{V}{f} \tag{2}$$

where, if V = inches per second, and f = cycles per second, λ is in inches. Table 1 compares frequencies and wavelengths in the audible range.

Table 1. Sound Frequencies and Wavelengths

Frequency f, cycles per sec	100	200	500	1000	2000	4000	6000	10,000
Wavelength, in.	132	66	26.4	13.2	6.6	3.3	2.2	1.3

A heterogeneous sound may be made up of wavelengths from this entire range, superimposed upon each other, the smaller traveling over the larger. Individual frequencies are called components. In noise work, sound should be considered in terms of its frequency.

SOUND VELOCITY IN SOLIDS is much higher than in air. In steel, it is about 17,000 ft per sec; in other building materials it is less, but much greater than in air.

FREQUENCY AND CHARACTER OF SOUND. Rumbles and boomings are of long wavelength. Ordinary whistling sounds are of intermediate wavelength. Tinkling noises and rattling of paper are of higher frequency. The whirring of a fan is a very complex noise in which, for small fans, higher frequencies predominate; for large fans and blowers a considerable proportion of low-frequency harmonics is present.

10. NOISE MEASUREMENT

SOUND-LEVEL METERS afford the best means of measuring noise. Specifications for sound-level meters have been established by the American Standards Association in *American Standard for Sound Level Meters for Measurement of Noise and Other Sounds*, Z24.3, 1944. Sound-level meters consist essentially of a microphone of uniform directional characteristic, a vacuum-tube amplifier, and a voltmeter. The meter reads sound level directly in decibels (see below). The amplifier has three networks corresponding to the ear response at 40 db, 70 db, and 100 db. At 100 db, the response is essentially flat. Commercial sound-level meters cover a range of 20 to 130 db. For the analysis of the sound the output of the sound-level meter can be connected to earphones, oscillographs, and recorders, or to harmonic analyzers (see below). Sound-level meters are manufactured by the General Electric Company, Schenectady, New York, the General Radio Company, Cambridge, Mass., and the Western Electric Company, New York, N. Y.

HARMONIC ANALYZER. A separate analyzer to determine frequency components can be used with the sound-level meter. Frequency components and their relative amplitudes are indicated. These analyzers are also useful for vibration analysis, when used with the vibration detectors mentioned before. They are made by the General Radio Company, the Hewlett Packard Company, Palo Alto, Calif., and the Western Electric Company.

TUNING FORKS. Much time can be saved in a frequency determination by using a set of tuning forks and noting beats. To determine, for example, whether or not a whistle from a gear is tooth-frequency noise, the note frequency is compared with the known frequency of gear-tooth impacts.

STETHOSCOPES. A physician's stethoscope, with a sharp point about 1 in. long fixed to the center of the diaphragm, placed against a vibrating structure is a very sensitive detector of noise transmission which otherwise cannot be heard. By tilting the point in different directions, the approximate direction of maximum amplitude can be detected. This instrument can locate node and loop areas on a sounding body of small vibration amplitude.

A steel diaphragm and point near a-c electrical apparatus will give a false indication. Disk and point and holder should be of phosphor bronze or other nonferrous metals.

VIBRATION DETECTORS. In connection with a sound analysis it is often necessary to study vibration patterns. Any of the vibration-measuring instruments mentioned on page 9-06 may be used. Many of the electrical pickups can be used with the sound-level meter, and very small vibration amplitudes, associated with sound production, can be directly read.

SOUND-LEVEL UNITS—DECIBELS. The sound-level unit almost universally adopted in commercial work is the decibel (db). Table 2 shows the meaning of the decibel scale in terms of: *(a)* everyday sounds; *(b)* vibrational energy in sound waves; *(c)* amplitude of motion of air particles in a 100- and a 1000-cycle wave; and *(d)* rise and fall of pressure in sound waves. The type of noise scale in Table 2 is constructed so that every increase of 10 db corresponds to ten times the noise intensity as shown in the third column. Thus a very loud noise of 115 db is ten billion times as energetic as a very low sound in perfectly quiet surroundings. This scale covers the whole audible sound range in 100 units, and distinguishes noises more nearly as the ear actually does than would a scale based upon energy or pressure units, as given in columns 3 and 6 of Table 2.

For practical purposes it is useful to remember that every 3-db increase in noise means that the intensity almost exactly doubles. If one noise is 12 db greater than another, the first noise intensity must be doubled four times, i.e., multiplied by 16, to equal that of the second in intensity, since $^{12}/_{3} = 4$. Two noises of equal intensity placed side by side give twice the intensity, or a total noise 3 db greater than either of them by itself regardless of their separate noise levels. Examples are shown in Table 3.

Table 2. Decibel Scales in Various Units

Decibels	Everyday Sounds	Sound Intensity (Threshold = 15 db)	Half Amplitude of Wave Motion, cm		Rise and Fall of Pressure in 1000-cycle Wave, dynes per sq cm
			Cycles		
			100	1000	
15	Very low	1			10^{-3}
25	Rustle of leaves	10	10^{-7}	10^{-8}	
35	Whisper	10^2			10^{-2}
45	Quiet residence	10^3	10^{-6}	10^{-7}	
55	Average residence	10^4			10^{-1}
65	Average business office	10^5	10^{-5}	10^{-6}	
75	Passenger automobile, 15 to 50 ft	10^6			1
85		10^7	10^{-4}	10^{-5}	
95	Motor trucks, 15 to 20 ft	10^8			10
105	Heavy street traffic in city	10^9	10^{-3}	10^{-4}	
115	Subway express passing through	10^{10}			10^2

Table 3. Comparison of Noise Values from Several Sources

Source 1	Source 2	Source 3	All Sources Together. Intensity of Source 1×	Source 1	Source 2	Source 3	All Sources Together. Intensity of Source 1×
35 db	35 db	0 db	2 = 38 db	40 db	40 db	0 db	2 = about 43 db
35 db	35 db	35 db	3 = about 40 db	40 db	40 db	43 db	4 = about 46 db
35 db	35 db	38 db	4 = about 41 db				

MATHEMATICAL DEFINITION. The difference in decibels between two noises of intensities I_1 and I_2 is defined by the mathematical relation:

$$\text{Difference in decibels} = 10 \log_{10} \frac{I_1}{I_2} \tag{3}$$

$$= 10 \log_{10} \frac{p_1^2}{p_2^2} = 20 \log_{10} \frac{p_1}{p_2} \tag{4}$$

where p_1 and p_2 are sound pressure amplitudes corresponding to I_1 and I_2. Equation 4 is multiplied by twice as large a constant as that of eq. 3 because sound intensity is proportional to the square of pressure amplitude of sound waves.

Equations like 3 and 4 involve only pressure and intensity ratios, and give decibel differences. It is thus necessary to define a zero point to fix scale values. Zero decibel's loudness level corresponds to sound produced by a 1000-cycle tone with a pressure amplitude of 0.0002 dyne per sq cm, or an intensity of 10^{-16} watt per sq cm.

At the time of selection of the reference level it was believed that this sound was just audible in a perfectly quiet room. On such a scale, sounds below audibility give negative decibel values. Table 3 is derived from these equations, as are the various relations brought out in the discussion of sound-level units above. (See Ref. 1.)

NOISE PREVENTION

A noise that cannot be prevented or greatly reduced at the source, by design or by damping, will radiate into the air either directly from the surface of the vibrating body or from

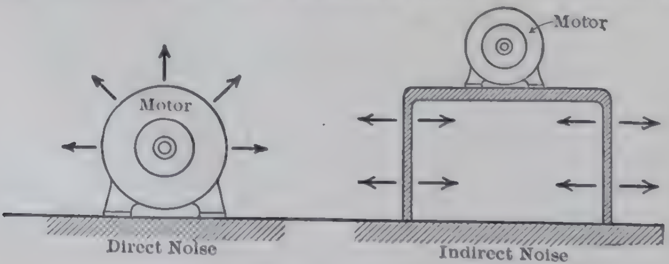

Fig. 1. Direct and indirect noise.

parts of the structure to which it is attached. Such noise radiation is indirect noise. See Fig. 1, where part of the motor noises radiate directly from the motor and part from panels of the room below, which may resonate to the frequency transmitted.

The following classification is useful when applying a preventive for noise:

Classification	Method		
Prevention at source	Design changes Damping		
Not readily preventable at source	Direct noise	Screening Absorption Filtration	Higher frequency range, 300 cycles and up
	Indirect noise	Isolation by suspension	Lower frequency range, under 300 cycles

A surface vibrating at small amplitude will radiate high frequencies directly into the air much more strongly than low. The latter require much larger vibrating surface area for direct radiation. Hence, in general, direct noises are of higher frequency than indirect; the 300-cycle limit in the classification is an average value.

11. NOISE PREVENTION AT SOURCE

DESIGN CHANGES involve the field of noisy apparatus. It is too large to be considered here, other than to cite a few instances. Remedies must come from studies by manufacturers.

Car-wheel Noise. Special car wheels with steel rims isolated from the rest of the wheel by rubber are being used on PCC trolley cars. Such wheels have greatly contributed to reducing the noise of cars.

Electric Motors. Special studies have produced designs with much lower a-c electrical hums.

Blower. Whistles from blowers in ventilating ducts usually are blade-frequency noises that can be eliminated at the source by design changes.

Gear Whistles. High-speed gearing can be greatly improved by accurate design to avoid impacts and by using helical instead of spur gears.

DAMPING. A sounding body, like a gear casing or small blower casing, can be quieted by covering it with a suitable damping material that has the ability to reduce vibrations.

Putty Lagging. A layer of nondrying putty 1 in. or more thick, covered with varnished cambric or similar material to prevent gradual drying of the putty, will sometimes greatly reduce noise. The putty exerts a powerful damping action, especially on high-frequency whistles and ringing noises, by reducing amplitude of case vibration. Lower-frequency rumbling noises are less strongly damped. The higher the frequency, the thinner may be the putty. Suitable nondrying putty can be made by any good chemist. It should have fairly high density and a binder to prevent its falling apart. Before application, the surface should be rubbed with a small amount of putty to improve adhesion.

Other Types of Lagging. Feltlike materials, when applied as lagging, have far less ability than putty to damp vibrations at the source, although they are sometimes effective as noise reducers. This effectiveness is due to their high sound-absorption coefficients, reducing the ability of a surface to radiate noise, and not to the fact that they reduce the amplitude of vibration. Although these materials are easier to apply, putty is more effective in such applications than any other material used by the author because of its power actually to reduce the surface vibration amplitude.

Resinous and tarlike materials, when applied as lagging, offer great friction to slow vibratory deflections of large amplitude. They are of relatively little use in damping high-frequency vibrations of small amplitude, aside from the increase in surface mass that they produce. These vibrations are so rapid that flow, with its attendant friction, does not occur. The relative vibration-absorption ability of different laggings is tested by coating the material on a steel diaphragm welded to a short pipe to support its edges. If the diaphragm is resonated by an electromagnet of variable frequency, it emits a loud sound unless the lagging is an effective damper. Impacting with a hammer is a good test if an electromagnet is not available. Commercially available materials are made by the Minnesota Mining & Manufacturing Co., and the Pittsburgh Plate Glass Co.

The correct use of acoustic felts is for the absorption of sound after sound waves are on the air. In this application, putty is of small value, compared to felt and similar materials.

12. SCREENING AND TRANSMISSION

SCREENING OF SOUND. Noise is screened either to confine it within a given space or to maintain a given space noise free. In either case the principle used is the same, i.e., to construct screens or walls highly resistant to noise transmission. The problem thus is one of noise transmission.

PROCESS OF TRANSMISSION. Sound is transmitted through a wall by air-pressure oscillations produced on its farther side by leakage or, more commonly, by oscillations produced by vibrations of the wall itself. This latter phenomenon usually occurs regardless of the presence of the former. Porous, feltlike materials transmit largely through leakage of wave oscillations.

Ordinary wood and plaster walls transmit by motion of the wall itself, or by vibration of portions of the wall. This is evident from Table 1, showing wavelengths of various sound frequencies. These are much in excess of the thickness of most walls, except those of high frequency, which are not readily transmitted. Sound waves of a given frequency in wall materials will be several times longer than in air, in proportion to the higher sound-transmission velocity of these materials. Only the highest frequencies in the audible range can exist as complete individual waves during transmission through ordinary wall.

Leakage. Small holes or cracks in a wall, otherwise highly resistant to noise transmission, will pass a surprising amount of sound, unless the crack is deep. Considerable damping action then is introduced by air friction on the crack sides. A soundproof room or box must have tight-fitting doors.

MEASUREMENT OF SOUND TRANSMISSION involves resonant effects depending upon mass, elastic characteristics and structure of the partition as determined by its dimensions, and reflection effects influencing the observations of the transmitted sound.

In engineering, a sound meter of the type described on p. 9-25 will indicate the intimate effect of the acoustics of the immediate surroundings. For example, the noise level in an ordinary room may fluctuate widely from place to place because of systems of standing sound waves which may be present. The ear will detect nodes and loops when the head is swinging back and forth if one or two fairly strong tones are present in a room.

FACTORS INFLUENCING TRANSMISSION. Noise is transmitted primarily by vibratory motion of a wall as a whole. Important factors in transmission prevention are mass per unit area and stiffness.

Stiffness is a trouble rather than an aid in the transmission resistance of walls, unless the wall is thick, of relatively small area, and unable to resonate to any objectionable noise harmonics. A small rigid metal case may resist noise transmission largely because of rigidity rather than mass per unit area.

Ordinary walls have various flexural resonant frequencies well below some objectionable noise harmonics. Stiffness can never aid such cases. It slightly increases wall-vibration amplitude, but this effect is negligible for relatively high frequencies.

A third important factor is wall structure. A double wall, with air space unbridged by rigid members, may resist noise transmission far more than a single wall of the same total weight per square foot.

DESIGN OF WALLS OF LOW TRANSMISSIBILITY. A double wall is more desirable than a single wall, being cheaper and less massive for the same transmission loss. A comparatively rigid skeleton of ordinary 2 by 4 in. studding should be used, with inner and outer walls hung from it by spring connections. These walls, of Celotex or similar material, should weigh 1 to 5 lb per sq ft. A thin layer of plasterlike reinforcement is helpful. Besides adding mass, it decreases porosity, which is an advantage. The Celotex may be reinforced by thin sheet iron. Sheet iron must not be used without Celotex, as it is subject to resonances.

Spring connectors eliminate the bridging effect of studding that results when the walls are directly nailed to it. Steel-spring connectors should be set on felt or rubber pads to reduce possible high-frequency vibration transmission through the springs. Such a wall has an air space of about 5 in., which is fair spacing. Air spacings of the order of 1 in. are much less effective, while spacing of more than 6 in. is usually unnecessary. (See Fig. 2.) If sound resistance required is not high, Celotex may be nailed directly to studding on both sides, but the advantage of the air space, which is large, is then much reduced.

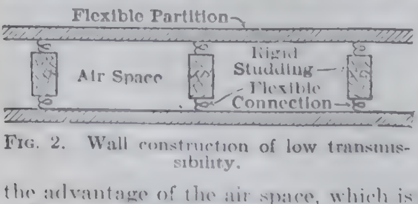

FIG. 2. Wall construction of low transmissibility.

A single wall should be of brick or masonry to have enough mass to be effective. A heavy masonry wall has high transmission resistance, but is expensive and cumbersome.

This type of wall is not particularly susceptible to resonances, its transmission resistance being due almost entirely to its mass.

Double walls of comparatively small mass, as recommended above, should have some damping, such as is contained in a material like Celotex, to avoid resonances. (See Ref. 2.)

TRANSMISSION LOSS. The aim of a soundproof wall or partition is to have sufficient transmission loss to be effective. This loss increases as the frequency rises. Table 4 gives an average transmission loss over the audible frequency range. It is of about the same order as that for a pure 500-cycle sound. Transmission loss is measured by the observed drop in sound intensity in decibels produced by the wall and is independent of the intensity of sound being screened. A wall causing a drop in noise level from 64 to 34 db will also cause a drop from 54 to 24 db, i.e., transmission loss is 30 db. For a double wall of the type first recommended the transmission loss is high, 40 to 60 db.

Table 4. Transmission Loss Produced by Various Partitions *

No.	Description	Transmission Loss, db	Lb per sq ft
1	Steel, 1/4 in. thick	30.0	....
2	Solid oak, 1 3/4 in. thick	20.9	....
3	Plate glass, single pane, 1/4 in. thick	22.8	....
4	Plate glass, 2 panes, 3/16 in. thick	19.7	....
5	Hair felt, 3 in. thick	11.8	....
6	3 layers 1-in. felt alternated with 4 layers building paper	27.9	....
7	2-in. gypsum tile, unplastered	20.2	10.4
8	3-in. gypsum tile, unplastered	23.7	14.2
9	4-in. clay tile, unplastered	28.8	17.0
10	4-in. clay tile, 1/2-in. plaster	30.8	22.0
11	8-in. brick wall, 1-in. plaster	46.1	88.0
12	Double 2-in. solid gypsum tile, unplastered unbridged, 4-in. separation	51.8	20.4
13	Same as 12, but bridged at top and bottom	46.9	20.4
14	Same as 12, inner faces lined with 1-in. felt	57.3	22.3
15	Staggered 2 by 4 in. wood studs, metal lath, 1/2-in. gypsum plaster	39.1	19.8
16	Same as 15, with 1/2-in. Celotex instead of metal lath	36.6	13.0

* Taken from work done under direction of Dr. Paul Sabine at Riverbank Acoustical Laboratory.

PRECAUTIONS. Several precautions are necessary in the design of transmission-resisting walls and screens after the design of the wall itself has been decided.

Transmission from Footing. Studding should be set on a layer of yielding material to prevent transmission to wall from ground or other support. A layer of rubber under the sill is good, but by itself becomes rather hard. By the principles of vibration isolation (see p. 9-19), a gravity elastic deflection of $^1/_8$ in. or more is desirable.

Transmission through Pipes and Ducts. Metallic pipes are effective transmitters of sound. Two or three pipes in a well-designed sound screen may greatly reduce its effectiveness. Transmission along a metallic pipe can be greatly reduced by rubber joints to prevent metallic contact of pipe sections. For air ducts, heavy canvas connections are effective. Direct transmission of sound through ventilating ducts may be considerable unless the inside of the duct is lined with sound-absorbing materials. (See below.)

Edges of Double Walls. Edges of the sound-insulating properties of elastically suspended wall partitions used with double walls must be free from rigid contacts with the frame, at the same time avoiding cracks through which sound can pass. Cracks can be stuffed with felt or similar material.

13. ABSORPTION OF SOUND

If directly radiated noise, as the noise in a business office or in a factory, cannot be screened, a decided reduction in the noise level can be made by means of sound-absorbing materials. Sound absorption takes place during wave reflection. It is measured by the fraction of the incident energy which disappears in a single reflection. An open window space reflects practically no sound and represents a maximum obtainable reduction.

Table 5 gives sound-absorption coefficients of various materials based on unity, as absorption of an open window. (See Ref. 3.)

Feltlike materials have high sound-absorbing power, as have certain porous materials. A good absorbent covering has a smooth surface layer of oilcloth or thin metal perforated with many holes, under which is a porous material. Such covering gathers less dust than a feltlike surface and is just as effective. An inexpensive method to increase the absorp-

Table 5. Sound-absorption Coefficients of Different Materials at Three Frequencies

Pitch			
Description	Coefficient		
	128 cps	512 cps	2048 cps

Reprinted by permission from Sound Absorption Coefficients of Architectural Acoustical Materials, *Bulletin IX*, published by the Acoustical Materials Association, 1947.

tion in a room is hanging of double cones made of sound-absorbing materials (obtainable from Johns-Manville Corporation). The density to be used is approximately one absorber per 4 sq ft. These double cones are, per area of sound-absorbing material, more efficient than materials placed on walls (see Ref. 4). Manufacturers of sound-absorbing materials are the Armstrong Cork Company, the Celotex Corporation, the Johns-Manville Corporation, the National Gypsum Company, the Owens-Corning Fiberglas Corporation, and the United States Gypsum Company.

The sound-absorbing materials are either cemented directly to the plaster or the concrete, or they are nailed to wood furring strips about 2 by 2 in. and 12 to 24 in. off center. The space between the sound-absorbing material and the wall may be filled with mineral wool. To obtain high absorption coefficients at low frequencies the spacing between sound-absorbing materials and wall should be increased. To obtain rooms with better than 90% sound absorption at frequencies below 120 cps, wedges of sound-absorbing materials approximately 3 ft by 4 ft long must cover the walls. (See Ref. 5.) The use of the correct amount of absorption on the interior walls of lecture and music halls comprises an important field of acoustic engineering, known as architectural acoustics. (See Refs. 6 and 7.)

Sound absorption and transmission resistance are entirely different processes. A good sound absorber, like felt, is a poor transmission preventive. Such material may be effectively used, however, as a lining of an enclosed space to reduce further the final noise level obtained by screening. If no sound-resisting walls were used with the absorbing layer, however, the noise level would be very much raised.

CALCULATION OF NOISE REDUCTION THROUGH ABSORPTION. When the noise level in a room and the sound absorption coefficients of its wall (Table 5) are known, the possible reduction in noise level through the use of more absorbent materials on the walls can be approximately calculated. From eq. 4,

$$\text{Decibels} = 10 \log_{10} \frac{a_2}{a_1} \tag{5}$$

To find a_1, multiply wall area of each part of the room by its absorption coefficient. If S = total area and if the coefficient of $^1/_6S = 0.03$, of $^1/_3S = 0.01$, and of $^1/_2S = 0.02$, then $a_1 = [(S/6) \times 0.03] + [(S/3) \times 0.01] + [(S/2) \times 0.02] = (S/6) \times 0.11$. Assume that the part of the surface whose coefficient is 0.02 is to be covered with an absorbent with a coefficient of 0.5. Then $a_2 = [(S/6) \times 0.03] + [(S/3) \times 0.01] + [(S/2) \times 0.50] = (S/6) \times 1.55$, and $a_2/a_1 = {}^{155}/_{11} = 14.1$. From eq. 5, db = 10 log 14.1 = 10 × 1.492 = 11.49. If all the walls and the floor were covered with such a material, $a_2 = (S/6) \times 3.00$; $a_2/a_1 = {}^{300}/_{11} = 29.2$, and db = 10 log 29.2 = 10 × 1.4654 = 14.65. Thus covering half the whole area would reduce the noise level by 11.49 db, but covering the whole area would reduce it only a little over 3 db more.

The conclusion is that, in reducing noise level by sound-absorbing materials on the walls, the greatest reduction is effected by the first part of the walls covered. After this, less and less improvement is obtained from a given area of absorption covering. It usually is sufficient to treat only part of the wall area of a noisy room. Sound-absorbing materials should be used in interiors so that they can reduce the noise by many back and forth reflections.

NOISE ABSORPTION IN DUCTS. Noise in ventilating ducts can be greatly reduced by linings of acoustic absorbent materials. This is particularly true of the higher-frequency rushing noises and hisses. As Table 5 shows, most available materials are effective only in the medium and high frequency ranges. For low-frequency absorption, Celocrete blocks have been found effective down to 30 cps. (See Acoustic Filters, below.)

14. FILTRATION OF SOUND

ACOUSTIC FILTERS IN GENERAL. When direct noise, containing definite notes or harmonics, is transmitted along ducts or through openings, it often is possible to eliminate objectionable harmonics completely by an acoustic filter that obstructs but little air flow or ventilation. Sound filters are of two classes: (1) low-pass filters which transmit low frequencies, but filter out the higher ones; (2) high-pass filters which do the opposite. A low-pass filter prevents transmission of the relatively high whistle often present in a ventilating duct. Low frequencies, predominant in explosive discharges, are filtered out by a high-pass filter, as an automobile muffler or Maxim silencer.

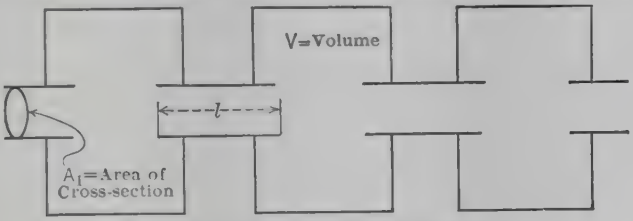

Fig. 3. Type 1, Low-pass acoustic filter.

Space is the usual limitation in filter applications, restricting for low-pass filters less than high-pass. Low-pass filters return sound energy to the source, where it dissipates itself through reflections, etc. High-pass filters must themselves dissipate the sound, this being an important reason for their comparative bulk. The individual stages of a filter must be considerably shorter than the wavelength of sound being filtered, each stage producing a definite amount of attenuation, as illustrated by the specific types of design which follow.

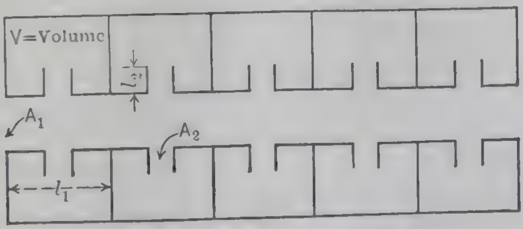

Fig. 4. Type 2, Low-pass acoustic filter.

LOW-PASS FILTERS may be divided into two classes of design. Figure 3 shows the first, and Fig. 4 the second. In designing a filter, the lower limit of frequency, f_0, is determined, below which it will transmit, and above which the filtering action begins.

For Type 1, Fig. 3,

$$f_0 = 4200\sqrt{\frac{A_1}{lV}} \tag{6}$$

where A_1 = area of cross section, square inches; l = length, inches; and V = volume, cubic inches, the symbols referring to Fig. 3.

For Type 2, Fig. 4,

$$f_0 = 4200 \sqrt{\frac{1}{V\{l_1/A_1 + 4[(l_2 + \frac{\pi}{4} D)/nA_2]\}}} \tag{7}$$

where D = width of orifice. Equation 7 can in most cases be replaced by the more approximate formula

$$f_0 = 2100 \sqrt{nA_2/V(l_2 + \frac{\pi}{4} D)} \tag{8}$$

where the symbols refer to Fig. 4, and n = number of passages per stage of sectional area A_2. If l_2 is very small such that A_2 is a simple orifice, the ratio $A_2/[l_2 + (\pi D/4)]$ is replaced by D, the diameter of the orifice. If there are several passages or orifices in each stage, $A_2/[l_2 + (\pi D/4)]$ or D must be multiplied by that number, n. Equation 8 becomes

$$f_0 = 2100\sqrt{nD/V}$$

For further details see Ref. 8.

Example of Design of Type 1 Filter. A whistle of about 400 cycles frequency is emitted from a tube of 1/4 sq in. cross-sectional area. A Type 1 filter (Fig. 3) should eliminate this sound. A_1 = 1/16 sq in., l = 3 in., V = 3 cu in. Figure 5 is a section of the filter in three stages, the two end tubes being shortened. From eq. 6, $f_0 = 4200\sqrt{1/16 \times 1/3 \times 1/3}$ = 350 cycles. The lower frequency limit of this filter being 350 cycles, the 400-cycle frequency should be eliminated. The wavelength of this sound is (1100/400) × 12 = 33 in., which is greater than the filter stage length. For higher frequencies, where the wavelength is below 6 in., the filtering action will fall off.

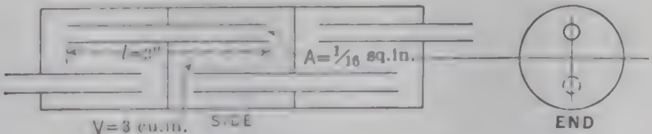

Fig. 5. Special filter design.

Example of Design of Type 2 Filter. Apply this type of design to the previous problem. Type 2 filters are more selective than type 1, *because filtering action is efficient only for frequencies near and just above the lower limiting frequency f_0.* Figure 6 is a design which should be satisfactory. Applying approximate eq. 8 and design data from Fig. 6, $f_0 = 2100\sqrt{1/4 \times 2 \times 1/16}$ = 372 cycles. The more exact eq. 7 will give a slightly lower frequency, but one sufficiently near 400 cycles to have a strong attenuating action on it. This design also consists of stages that are short compared with the wavelength of the sound to be filtered. The filtering action of type 1 low-pass filter covers a broader range of frequency than type 2 and is very efficient. Type 2, however, can sometimes be designed to occupy considerably less space than type 1. The preferred type depends on conditions to be met.

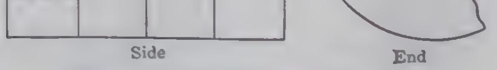

Fig. 6. Special low-pass filter design.

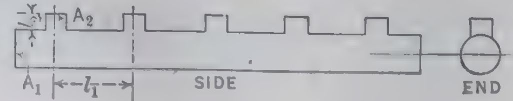

Fig. 7. High-pass filter.

HIGH-PASS FILTERS are not so efficient in performance as low-pass filters and are, as a rule, more bulky. Figure 7 is a typical high-pass filter of simple design. The limiting frequency, above which such a filter ceases to perform, is

$$f_0 = 2100 \frac{\sqrt{nA_2}}{A_1 l_1 l_2} \tag{9}$$

The symbols are shown in Fig. 7, and, as before, $A_2/l_2 = D$ = hole diameter when l_2 is small, and n = number of holes of area A_2 per stage.

This type of filter functions through successive side leakage of pressure waves as they pass through the tube. When the wave escapes from the tube end, its pressure amplitude and its intensity are greatly reduced. An appreciable amount of sound, however, escapes through the side holes. Good high-pass filters require an outer shell of considerably larger diameter than the inner tube, the interspace being stuffed with a damping material such as metal wool or shavings. Steel wool will rust in gas-engine exhaust mufflers.

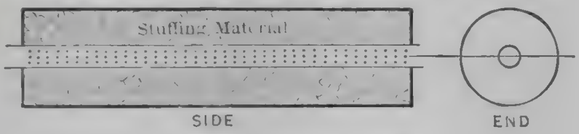

Fig. 8. Explosion muffler.

Figure 8 is a cross section of an efficient muffler that has considerably less back pressure than the baffle-type automobile muffler. For high attenuation, many small holes are better than the few large ones of Fig. 6. The use of eq. 9 is not necessary for explosion mufflers, because these filters always attenuate low-frequency impulse waves. This equation will show that the limit f_0, above which attenuation ceases, is well above these low frequencies, being seldom below 100 cps.

PERFORMANCE. An ideal sound filter produces a certain percentage drop in sound intensity per stage for every frequency within its range of attenuation. Thus, a six-stage low-pass filter may attenuate a 300-cycle tone by 4 db per stage, or 24 db in all. A sharply tuned type 2 low-pass filter will attenuate much more. Attenuation in decibels per stage is independent of the initial sound intensity.

Performance of a low-pass filter sometimes is disappointing. Tube-resonance effects must be avoided. A tube of length equal to a multiple of one-half the wavelength of sound of a given frequency will resonate to that frequency. An otherwise well-designed filter may not perform well if such effects enter; placing it in different positions in the duct usually will eliminate them. High-pass filters, as mufflers, are less subject to this trouble. A fairly good knowledge of the elementary principles of sound is desirable in making sound-filter applications. For a discussion of sound filtration, see Refs. 9 and 10.

15. INDIRECT NOISE

Indirect noise is the result of transmission, through a structure, of sound vibration from an exciting source which may be quite remote. An ordinary structure has ability to transmit vibration waves a long distance almost perfectly noiselessly to some point. For example, a panel with the same natural frequency as the wave may resonate with surprising strength. The source of vibration sometimes is hard to find. The treatment of indirect noise is to isolate the source by elastic suspension. Vibration isolation is discussed on p. 9-19. The same methods apply to cases of noise isolation.

SCREWS AND SCREW FASTENERS

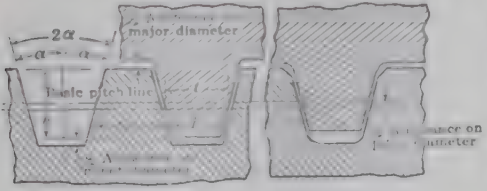
CLASSIFICATION. Screws and bolts may be classified, according to use, in two general groups. A. Screws for transmitting power. B. Screw fastenings. Class B may be further subdivided into (1) bolts, (2) studs, (3) machine screws, (4) cap screws or tap bolts, (5) set screws, (6) T-head bolts, (7) coupling bolts, (8) hook bolts, (9) automobile bolts, (10) carriage bolts, (11) stove bolts, (12) expansion bolts, (13) foundation bolts, (14) eye bolts, (15) stay bolts, (16) patch bolts, (17) wood screws, and (18) lag screws and other special screws and bolts.

FORM OF THREAD depends on the service required and on the engineering standards of the country in which the thread is used. In general, the full V thread and the modified V thread are best adapted for fastenings. These combine strength and cheapness; the inefficiency of the V thread in transmitting power lessens the liability of unscrewing. Power transmission or translating threads in general are provided with smaller thread angles to increase the efficiency.

1. TRANSLATING THREADS

TRANSLATING THREAD STANDARDS. Five basic translating screw thread series are covered by ASA standards: Acme, Acme stub, 60-degree stub, modified square, and buttress.

Acme Screw Threads. Originally developed for the purpose of producing transverse motions on machine tools, Acme screw threads are now used extensively for a variety of purposes. Good current practice provides for two types of applications: general purpose and centralizing (see Fig. 1). Basic dimensions of the Acme form of thread are (see Fig. 1): angle of thread, $2\alpha = 29$ degrees; basic height of thread, $h = 0.5p$; thickness of thread at pitch line, $t = 0.5p$; basic width of flat, $F = 0.3707p$; where p = pitch, inches. The most generally used pitches are listed in Table 1. Basic proportions of recommended diameter and pitch combinations using Acme threads are given in Table 2.



General purpose Centralizing

FIG. 1. Acme thread forms.

Table 1. General-purpose Acme Threads, Standard and Special Pitches *

Threads per Inch	Pitch, p, in.	Threads per Inch	Pitch, p, in.	Threads per Inch	Pitch, p, in.
16	0.06250	6	0.16667	2	0.50000
14	0.07143	5	0.20000	1 1/2	0.66667
12	0.08333	4	0.25000	1 1/3	0.75000
10	0.10000	3	0.33333	1	1.00000
8	0.12500	2 1/2	0.40000		

* Recommended diameter and pitch combinations are given in Table 2.

General-purpose Acme threads are of three classes, 2G, 3G, and 4G, which differ from each other in pitch diameter allowances and tolerances (see American Standard). Class 2G is preferred for general-purpose assemblies, classes 3G and 4G being intended for applications requiring less backlash and endplay.

Centralizing Acme threads are of five classes, 2C, 3C, 4C, 5C, and 6C. Class 2C provides the maximum endplay or backlash. For centralizing threads the allowance at the major diameter is smaller than that at the pitch or minor diameters, the concentricity of screw and nut thus being controlled at the major diameter. For allowances, tolerances, and other details, see American Standard, *Acme Screw Threads*.

Acme Stub Thread. Intended for unusual applications where a coarse-pitch thread of shallow depth is required because of mechanical or metallurgical considerations, this

For general-purpose and centralizing classes 2C, 3C, and 4C, basic pitch diameter $E = D - h$; basic minor diameter $K = D - 2h$.

For centralizing classes 5C and 6C, basic pitch diameter $E = B - h$; basic minor diameter $K = B - 2h$.

For stub Acme, basic pitch diameter $E = D - h'$; basic minor diameter $K = D - 2h'$.

series has the same angle of thread (29 degrees) as the Acme, but the basic depth is reduced to $h = 0.3p$. Basic width of flat is $F = 0.4224p$.

Recommended combinations of nominal diameter and pitch for stub Acme screws and nuts are the same as for the Acme, Table 2. Only one class of thread is established for general usage, that corresponding to class 2G for general-purpose Acme threads (see the standard). If a fit with less backlash is required, tolerances and allowances used in other classes of Acme thread may be used.

Two modified stub Acme thread forms are recognized in the Standard. Form 1 employs a basic thread height $h = 0.375p$ and Form 2 a basic thread height $h = 0.25p$. Basic widths of flat at crest of internal thread are, respectively, $F = 0.4030p$ and $F = 0.4353p$ for Forms 1 and 2.

60-Degree Stub Thread. Angle between sides of thread is $2\alpha = 60$ degrees, and basic depth is $h = 0.433p$. Basic width of flat at crest of internal thread is $F = 0.250p$. (See ASA B1.3-1941.)

Modified Square Thread. Included angle is $2\alpha = 10$ degrees, and basic depth of thread is $h = 0.5p$ (same as the Acme). Basic width of flat is $F = 0.4563p$. The 10-degree angle results in a thread which, for practical purposes, is equivalent to a "square" thread but is capable of economical production. (See ASA B1.3-1941.) The square thread ($2\alpha = 0$, $h = 0.5p$, $t = 0.5p$) is expensive to make and is not easily compensated for wear

Buttress thread (Fig. 2) is a nonsymmetrical thread intended for applications with exceptionally high stresses in one direction only, along the thread axis. Because the thrust side of the thread is very nearly perpendicular to the thread axis, the radial component of thrust is a minimum, making this form of thread particularly suitable for tubular members which have to be screwed together. Applications include breech mechanisms of large guns and airplane propeller hubs.

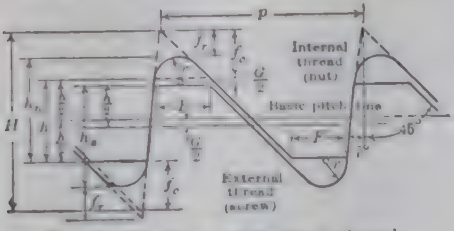

FIG. 2. Basic form of buttress thread.

Thread form is shown in Fig. 2, the dimensions being as follows: height of sharp V thread $H = 0.89064p$; basic height of thread $h = 0.4p$; root radius $r = 0.12055p$; root truncation $f_r = 0.13946p$; crest truncation $f_c = 0.24532p$; crest width $F = 0.27544p$; G = allowance; height of thread in nut h_n = height of thread in screw $h_s = 0.50586p$. Pressure flank angle, measured in an axial plane, is 7 degrees from the normal to the axis, and the trailing flank angle is 45 degrees.

Inasmuch as buttress threads are applied mainly to specially designed components, there is no standard series of diameter-pitch combinations. However, it is recommended that nominal major diameters be selected from the geometric series:

1
1 1/8
1 1/4
1 3/8
1 1/2
1 3/4
2
2 1/4
2 1/2
2 3/4
3
3 1/2
4
4 1/2
5
5 1/2
6
7
8
9
10
11
12
14
16
18
20
22
24

Pitches, likewise, should be selected from the geometric series having the following threads per inch:

20
16
12
10
8
6
5
4
3
2 1/2
2
1 1/2
1 1/4
1

It is suggested that diameter and pitch combinations be within the following ranges, using the foregoing preferred numbers:

Diameter Range, inches	Associated Pitches, threads per inch	Diameter Range, inches	Associated Pitches, threads per inch
1 to 2 1/2	20 to 6	6 to 10	12 to 2 1/2
2 1/2 to 4	20 to 5	10 to 16	8 to 1 1/2
4 to 6	16 to 4	16 to 24	6 to 1

A modified form of the foregoing buttress thread may be employed where manufacture with a single-point cutting is general practice or where the 7-degree pressure flank may produce high bursting stresses. It conforms as closely as practicable to the standard form swung through an angle of 7 degrees to give a pressure flank angle of zero and an included angle of 50 degrees.

EFFICIENCY OF SCREW THREADS. If a torque T applied to a screw produces an axial force F, the efficiency is

$$e = \frac{Fr \tan \lambda}{T} \tag{1}$$

where r is the pitch radius of the screw and λ is the lead or helix angle, calculated from the relation

$$\tan \lambda = \frac{L}{2\pi r} = \frac{np}{2\pi r} \tag{2}$$

where L is the lead $= np$, p being the pitch and n the number of thread starts, if a multiple thread. For a single thread, $n = 1$. The relation between torque and force is

$$\frac{T}{Fr} = \frac{\dfrac{f_1}{\cos\phi} + \tan\lambda}{1 - \dfrac{f_1}{\cos\phi}\tan\lambda} + f_2\frac{r_c}{r} \tag{3}$$

where r_c is the radius of the thrust collar, f_1 is the coefficient of friction between screw and nut, f_2 is the coefficient of friction at the thrust collar, and ϕ is the pressure flank angle. For symmetrical threads, $\phi = \alpha = 14\frac{1}{2}$ degrees in the Acme series, and 30 degrees in the Unified and American screw thread series. Values of λ are given in Tables 2 to 8 for various thread series. Pitch radius $r = E/2$.

2. SCREW THREAD STANDARDS FOR FASTENERS

Screw thread standards in the United States, Canada, and Great Britain were unified through prolonged joint efforts which culminated in the signing of a declaration of accord in 1948. The *Unified and American Screw Threads* standard (ASA B1.1-1949) is closely similar to the American National standard formerly used in the United States. Thread angle and depth of V thread are identical, as is the truncation ($h/8$) at the major diameter (Fig. 3). Basic pitch diameters therefore are identical for the same diameter and pitch. Threads made to old and new standards are interchangeable.

The new standard emphasizes the desirability of a rounded root contour for the external or bolt thread (as in the British Whitworth standard) but permits a flat root when using unworn tools (as in the American National Standard). Crest of the external thread may be flat or rounded whereas the internal or nut threads have flat crests, and flat roots which may become rounded as tools wear.

For details of the old American National thread see p. 10-28, or the eleventh edition of Kent's *Mechanical Engineers' Handbook* (*Design, Shop Practice* Volume), p. 9-04, or ASA B1.1-1935.

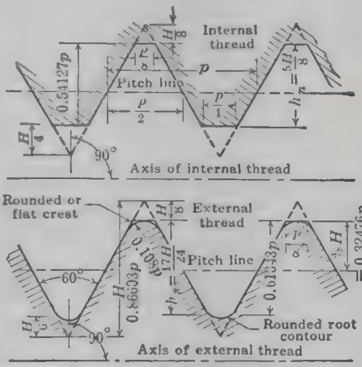

Fig. 3. Unified and American internal and external screw thread design forms, maximum metal condition.

UNIFIED FORM OF THREAD. The unified form of thread is illustrated in Fig. 3. The included angle between the flanks of the thread, measured in an axial plane, is 60 degrees, and the line bisecting this 60-degree angle is perpendicular to the axis of the screw thread. Formulas for the basic thread dimensions are given in Fig. 3. Basic depth of thread engagement is $h_e = 0.54127p$

THREADED PARTS have either an external thread (screw) or an internal thread (nut). Basic sizes of the principal dimensions are given by the following formulas which, in conjunction with Tables 3, 4, 5, 6, 7, 8, and 9, may be used to calculate basic pitch diameters and minor diameters. For limiting dimensions, see Tables 10, 11, 12, 13, and 14.

Table 3. Unified and American Coarse-thread Series—UNC and NC

(ASA B1.1-1949. All dimensions in inches.)

For pitch diameter, see eq. 4; for basic minor diameter of external threads, see eq. 5.

* See eq. 8.

† Not included in the Unified standard.

Major diameter (D) of a threaded screw or nut is the largest diameter of the screw thread. The basic major diameter, which is the minimum major diameter of the internal or nut thread, is equal to the nominal size.

Pitch diameter (E) is the diameter of an imaginary cylinder whose surface would pass through the thread profiles at such points as to make the width of the groove equal to one-half the basic pitch. On a perfect thread this occurs at the point where the widths of the thread and groove are equal. The basic pitch diameter, which is the minimum pitch diameter of the internal or nut thread, is given by the formula

$$E = D - 0.64952p = D - \frac{0.64952}{n} \tag{4}$$

For pitch diameter, see eq. 12; for basic minor diameter of external threads, see eq. 13.

* See eq. 8.

where p is the pitch, inches; and n is the number of threads per inch. See Tables 3 to 8 for values of D and n for standard series. Table 9 lists recommended combinations of D and n for special, nonstandard applications.

Minor diameter (K) is the smallest diameter of the screw thread. Basic minor diameter of the *external* or screw thread (K_s) is given by the formula

$$K_s = D - 1.22687p = D - \frac{1.22687}{n} \tag{5}$$

Basic minor diameter of the *internal* or nut thread (K_n) is given by the formula

$$K_n = D - 1.08253p = D - \frac{1.08253}{n} \tag{6}$$

See Tables 3 to 8 for values of K_n for standard series.

Lead angle (λ) is the angle made by the helix of the thread at the pitch line with a plane perpendicular to the axis. Lead angle at the basic pitch diameter is given by the formula

$$\lambda = \tan^{-1}\frac{p}{\pi E} = \tan^{-1}\frac{1}{n\pi E} \tag{7}$$

See Tables 3 to 8 for values of λ for standard thread series.

Stress area (A_s) is the assumed area of an externally threaded part, used for the purpose of computing tensile strength. It is given by the formula

$$A_s = 3.1416\left(\frac{E_m + K_m}{4}\right)^2 \tag{8}$$

Table 8. American 16-pitch Thread Series—16N

where E_m = mean pitch diameter and K_m = mean minor diameter, both based on class 3 tolerances. See Tables 3 to 8 for values of A_s for standard thread series.

SCREW THREAD SERIES. Six standard series of threads are included in the *Unified and American Screw Threads* standard, ASA B1.1-1949. Of these only two, the coarse and fine thread series, are included in the Unified standard used also in Canada and Great Britain. Following are the six series.

Coarse-thread Series (UNC and NC). Diameter-pitch combinations of the Unified and American coarse-thread series are given in Table 3. The series is recommended for general use in engineering work where conditions are favorable to quick and easy assembly of parts with bolts, screws, and other threaded components, and where a fine thread is not required. It is the former United States Standard supplemented in the sizes below 1/4 in. by a part of the Standard Proportions for Machine Screws established by the ASME in 1907. Limiting dimensions are given in Tables 10, 11, 12, 13, and 14.

Fine-thread Series (UNF and NF). Table 4 lists the diameter-pitch combinations for this series, which is recommended for general use in automotive and aircraft work and where special conditions require a fine thread. The fine-thread series is the former Regular Screw Thread Series established by the SAE in 1911, supplemented below 1/4 in. by sizes of the ASME Standard Proportions for Machine Screws. Limiting dimensions are given in Tables 10, 11, 12, 13, and 14.

Extra-fine-thread Series (NEF). This series (see Table 5) is intended for special uses where thin-walled material is to be threaded, where thread depth of nuts clearing ferrules,

(Continued on p. 10-23)

* The maximum dimensions of threads which are electroplated or have coatings of similar thickness will be increased by the amount of the allowance.

[1] For semifinished and finished screws and bolts, threaded portion only.

[2] For unfinished hot rolled material threaded portion only.

1 3/4 ‡	.0016	.0094	.0090	.0053	.0069	.0059	.0041	.0085	.0080
2 ‡	.0016	.0094	.0090	.0054	.0070	.0061	.0043	.0085	.0080

Values are based on a length of engagement of nine threads.

* Allowances are zero for classes 2 and 3.

† Major diameter of internal threads may extend to a $p/24$ flat.

‡ Unified threads, in classes 2A and 2B.

couplings, flanges, etc., must be held to a minimum, and where maximum practicable number of threads is required within a given thread length. The series is the same as the former SAE fine series and the present SAE extra-fine series. Allowances and tolerances for various fits are given in Table 15. Limiting dimensions may be calculated from eqs. 4 to 6 and 18 to 27, or may be obtained from the standard (ASA B1.1-1949).

Eight-thread Series (8N). This series (see Table 6) has application for fastenings which require that an initial tension be set up by elastic deformation of the fastening and of the components which it holds together. Examples are bolts for high-pressure pipe flanges and cylinder-head studs which hold against pressure. To secure proper initial tension the pitch should not increase with diameter; otherwise the torque required to assemble the fastening would become excessive in the larger sizes. To meet this need, the 8-thread series has come into general use in many classes of engineering work as a substitute for the coarse-thread series.

For the 8-thread series, eqs. 4, 5, and 6 become, respectively,

$$E = D - 0.0812 \tag{9}$$

$$K_s = D - 0.1534 \tag{10}$$

$$K_n = D - 0.1353 \tag{11}$$

Limiting dimensions are given in Tables 11, 13, and 14.

Twelve-thread Series (12N). This series (see Table 7) is used in machine construction for thin nuts on shafts and sleeves. It is the coarsest thread in general use that will permit a threaded collar to slip over a shaft and screw onto a threaded shoulder, the difference in diameter between shoulder and shaft being 1/8 in. Sizes of 12-pitch threads from 1/2 in. up to and including 1 3/4 in. are used in boiler practice, which requires that worn stud holes be retapped with a tap of the next larger size, the increment being 1/16 in. throughout most

* Allowances are zero for classes 2 and 3.

† Major diameter of internal threads may extend to a $p/24$ flat.

‡ Unified threads, in classes 2A and 2B.

§ These are standard sizes of the UNC or UNF series and tolerances are the same as for those series, being based on a length of engagement equal to the nominal diameter. All other classes 2A and 2B tolerances and all classes 2 and 3 tolerances for sizes larger than 1 1/2 in. are based on a length of engagement of 9 threads.

of the range. Die-head chasers for sizes up to 3 in. are readily available. The 12-thread series also provides continuation of the fine-thread series (UNF) in diameters larger than 1 1/2 in. Allowances and tolerances for various fits are given in Table 16.

Table 17. 16-pitch Thread Series (16UN and 16N) Allowances and Tolerances

6 ‡	.0019	.0094	.0090	.0062	.0081	.0081	.0057	.0085	.0080

Values for classes 2A and 2B are based on a length of engagement equal to the nominal diameter for the 3/4 in. size and a length of engagement of 9 threads for larger sizes, and for classes 2 and 3 on a length of engagement of 9 threads.

* Allowances apply to external threads class 2A only.

† Major diameter of internal threads may extend to a $p/24$ flat.

‡ Unified threads, in classes 2A and 2B.

For the 12-thread series eqs. 4, 5, and 6 become, respectively,

$$E = D - 0.0541 \tag{12}$$

$$K_s = D - 0.1022 \tag{13}$$

$$K_n = D - 0.0902 \tag{14}$$

Limiting dimensions may be calculated from the foregoing equations in conjunction with eqs. 18 to 27 and Table 16 or may be obtained from the standard (ASA B1.1-1949).

Sixteen-Thread Series (16N). This series (see Table 8) is intended for applications which require a relatively fine thread such as threaded adjusting collars and bearing retaining nuts. It also provides continuation of the extra-fine series (NEF) in diameters larger than 2 in. Allowances and tolerances for various fits are given in Table 17.

For the 16-thread series, eqs. 4, 5, and 6 become, respectively,

$$E = D - 0.0406 \tag{15}$$

$$K_s = D - 0.0767 \tag{16}$$

$$K_n = D - 0.0677 \tag{17}$$

Limiting dimensions may be calculated from the foregoing equations in conjunction with eqs. 18 to 27 and Table 17. Tabulated values are given in ASA B1.1-1949.

Special Threads (UNS, UN, or NS). Diameter and pitch combinations not included in the coarse-thread (UNC and NC), fine-thread (UNF and NF), and 8-thread (8N) series are designated as special threads. Special threads, therefore, include the national extra-fine (NEF), the 12-thread (12N), and 16-thread (16N) series as well as any combinations of diameter and pitch not covered by the six series listed in Tables 3, 4, 5, 6, 7, and 8.

Where requirements cannot be met by any of the combinations in these six series, it is recommended that one of the combinations listed in Table 9 be selected. Basic dimensions for special combinations may be calculated from eqs. 4, 5, 6, 7, and 8. The standard (ASA B1.1-1949) lists limiting dimensions of threads conforming to Tables 6, 7, 8, and 9 for classes 2A, 2B, 2, and 3 with thread engagement equal to $9p$.

Table 18. Limiting Dimensions of Screw Threads for High-strength Bolting, Class 7 Fits

* Pitch diameter tolerances include errors of lead and angle.

High-strength bolting threads (ASA B1.4-1945) employ the coarse-thread series for sizes 1 in. and smaller, and the 8-thread series for larger sizes (see Table 18). Developed to provide a thread that could readily be machined from alloy steels and with an allowance permitting the application of lubricant during assembly, this thread has been applied to many services, both hot and cold, where high-tensile stresses are produced when the joints are made up.

SCREW THREAD DESIGNATION. For brevity on drawings, etc., screw threads are designated by the nominal size (diameter in inches, or screw number) followed by the number of threads per inch, the initial letters of the thread series, and the screw-thread class (see next paragraph) with or without the pitch diameter tolerances or limits of size. For example,

$$1/4 - 20 \text{ UNC} - 2\text{A}$$

denotes a $1/4$-in. nominal-size screw having 20 threads per inch, which is in the coarse-thread series (UNC). The term 2A indicates class 2A tolerance and allowance, this being an external thread. Unless specifically designated by the letters LH for left-hand, the screw is understood to be right-handed. If a standard thread is modified, the word "modified" should be added with an asterisk, and the nonstandard feature or dimension of the thread enclosed in brackets and likewise marked with an asterisk.

SCREW THREAD CLASSES are distinguished from each other by the amount of tolerance and allowance specified. The unified standard includes classes 1A, 2A, and 3A for external threads and classes 1B, 2B, and 3B for internal threads. In addition, the American standard includes classes 2 and 3 for both external and internal threads, a holdover from the old National standard.

Classes 2A and 2B are the recognized standards for normal production of screws, bolts, and nuts and are suitable for a wide range of applications. See Fig. 4. The allowances and tolerances provide a clearance under all conditions; the minimum clearance is such as to minimize galling and seizure in assembly and use. Plating applied to external threads may project into or fill this space.

Classes 2A and 2B have been established for all thread series. Limiting dimensions of coarse, fine, and 8-thread series of these classes are given in Table 11. Allowances and tolerances for other series are given in Tables 15, 16, and 17.

Classes 1A and 1B in combination provide a fit suitable for threaded parts where quick and easy assembly is necessary, even when the threads are bruised or dirty, as in ordnance and certain special applications. See Fig. 4. Tolerances are 50% greater than on classes 2A and 2B, but the allowance on 1A is the same as on 2A. Classes 1A and 1B have been established for the coarse- and fine-thread series only, Table 10.

FIG. 4. Tolerances, allowance, and crest clearances for Unified and American classes 1A, 2A, 1B, and 2B. For classes 3A, 3B, 2, and 3 the allowance is zero.

Classes 3A and 3B are suitable for applications requiring close fit and accuracy of lead and angle of thread. Such fits are obtainable only by the use of high-quality production equipment supported by efficient gaging and inspection. No allowance is provided on external threads (3A), and the tolerances are 75% of those for classes 2A and 2B. Classes 3A and 3B have been established for the coarse- and fine-thread series only, Table 12.

Classes 2 and 3, held over from the earlier National standard during the transition to the unified standard, correspond in general application to classes 2A and 2B, and 3A and 3B, respectively. However, no allowance is provided on either class 2 or class 3. Tolerances for class 3 are approximately 70% of class 2 tolerances. Limiting dimensions of coarse, fine, and 8-pitch threads of class 2 are given in Table 13, and of class 3 in Table 14. Allowances and tolerances for other series are given in Tables 15, 16, and 17.

Class 4 Fit. Included in the American National standard, ASA B1.1-1935, but not in the Unified and American Standard, ASA B1.1-1949, class 4 results in selective assembly type of fit. It is not adaptable to quantity production and was intended only for unusual and exacting requirements. With a maximum screw and a minimum nut there is actual interference of metal.

Class 5 Fit. Based on experimental data developed by the National Bureau of Standards for permanent assembly of steel studs in hard material, class 5 results in interference. It is included in the Bureau's *Handbook H-28*, 1944 edition.

Class 7 Fit. This designation is applied to the screw-thread fit used on High Strength Bolting (ASA B1 4-1945). The nuts are identical with class 2 nuts of equal diameter and pitch. Allowance on the bolts is obtained by making the maximum pitch diameter of the screw smaller than the minimum pitch diameter of the nut by an amount equal to the difference between the class 2 and class 3 tolerances. The screw has a class 3 tolerance so that the minimum pitch diameter of the screw is equal to the minimum pitch diameter of a class 2 screw. Limiting dimensions of High Strength Bolting screws and nuts employing the class 7 fit are given in Table 18.

Limiting dimensions for all thread series other than the coarse, fine, and 8-pitch (which are given in Tables 10, 11, 12, 13, and 14) may be calculated from the basic dimensions (eqs. 4, 5, and 6) in conjunction with Tables 15, 16, and 17, which give the allowances and tolerances. The following equations give the relationships between basic dimensions, allowances and tolerances, and limiting dimensions (see also Fig. 4):

For external threads:

$$\text{Major diameter, max} = D - a \tag{18}$$

$$\text{Major diameter, min} = D - a - t_{ds} \tag{19}$$

$$\text{Pitch diameter, max} = E - a \tag{20}$$

$$\text{Pitch diameter, min} = E - a - t_{es} \tag{21}$$

$$\text{Minor diameter, max} = K_s - a \tag{22}$$

Minor diameter, min Not specified

For internal threads:

$$\text{Minor diameter, min} = K_n \tag{23}$$

$$\text{Minor diameter, max} = K_n + t_{kn} \tag{24}$$

$$\text{Pitch diameter, min} = E \tag{25}$$

$$\text{Pitch diameter, max} = E + t_{en} \tag{26}$$

$$\text{Major diameter, min} = D \tag{27}$$

Major diameter, max Not specified

where D is the basic major diameter (Tables 3, 4, 5, 6, 7, 8, and 9); E, K_s, and K_n are the basic dimensions calculated from eqs. 4, 5, and 6; a is the allowance; t_{ds} is the major diameter tolerance for external (screw) thread; t_{es} is the pitch diameter tolerance for external (screw) thread; t_{en} is the pitch diameter tolerance for internal (nut) thread; and t_{kn} is the minor diameter tolerance for internal (nut) thread.

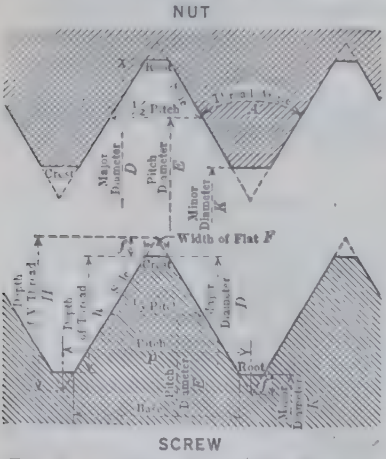

Fig. 5. American National thread form.

For complete data on tolerances, allowances, and limiting dimensions of threads other than those covered by Tables 3, 4, 5, 6, 7, and 8, the standard (ASA B1.1-1949) should be consulted.

In applying the foregoing formulas it should be noted that the allowance a applies only to classes **1A and 2A. The allowance is zero for class 3A, and also for classes 2 and 3.**

AMERICAN NATIONAL form of thread, which the Unified and American thread form replaces, is that previously known as the United States Standard or Sellers profile (Fig. 5). Basic angle of thread, measured in an axial plane, is 60 degrees; basic width of flat at the root and crest of the thread is $F = 0.125p = 0.125/n$; basic depth of the thread form is $h = 0.649519p = 0.649519/n$, where $p =$ pitch, inches, and $n =$ number of threads per inch. Complete information is given in ASA B1.1-1935.

Clearance at Minor Diameter. Clearance is provided at the minor diameter of the screw thread in the nut by truncation such that the basic depth of thread is reduced by one-sixth or more, depending on the size and pitch.

Clearance at Major Diameter. Clearance at the major diameter of the screw thread in the nut is provided by decreasing the depth of the truncation triangle any desired amount down to one-third its theoretical value.

Interchangeability. American National threads are interchangeable with the Unified and American threads. Where American National threads are specified it is recommended that users accept the new classes as optional, and vice versa during the transition.

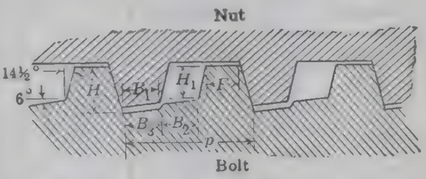

Fig. 6. Dardelet relieved thread (unlocked).

DARDELET THREAD (Lock Thread Corporation). Similar to the Acme, with an included thread angle of 29 degrees, the Dardelet thread has smaller depth and thickness in relation to the pitch, as well as inclined flats at the roots of the bolt thread and inclined crests on the nut threads (Fig. 6). Approximate proportions are as follows, where n = number of threads per inch: pitch $p = 1/n$; $B_1 = 0.290p$; $B_2 = 0.272p$; $B_3 = 0.282p$; $H = 0.349p$; $H_1 = 0.238p$; and $F = 0.282p$. The 6-degree angle of inclination provides a wedging action when the nut is tightened, locking the two elements against vibration. Dardelet threads are made in a coarse-thread and a fine-thread series (Table 19).

Table 19. Diameter and Pitch Combinations Using Dardelet Threads

Size or Diameter	Threads per Inch		Size or Diameter	Threads per Inch	
	Coarse	Fine		Coarse	Fine
No. 8	..	24	5/8	8	13
No. 10	..	24	11/16	8	12
No. 12	..	24	3/4	8	12
No. 14	..	20	13/16	7	12
1/4	16	20	7/8	7	11
5/16	14	18	1	6	10
3/8	12	16	1 1/8	5	8
7/16	11	16	1 1/4	5	8
1/2	10	16	1 3/8	5	7
9/16	9	14	1 1/2	4	6

LOK-THRED (Lock Thread Corp.). Similar to the Unified and American Standard, the included angle of the thread being 60 degrees, this thread differs in having smaller depth and slightly less thickness in relation to the pitch, as well as 6-degree inclined spiral flats at the root of the screw thread (Fig. 7). Thread depth, Y, of the external (screw) thread is either 60 or 70% of that of the American National standard, depending on the application. The 70% ($Y = 0.7h$) standard is recommended for cap screws and bolts and the 60% ($Y = 0.6h$) for studs. It will be noted from Fig. 7 that the width of root, T, for the two series is $0.5p$ minimum and $0.425p$ minimum, respectively, as against $0.125p$ for the Unified thread.

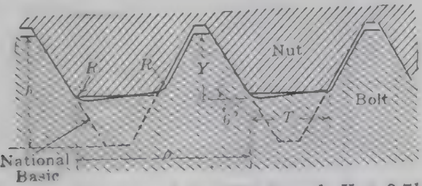

Fig. 7. Lok-Thred for 70% thread: $Y = 0.7h$, $T = 0.5p$, and $R = 0.137p$. For 60% thread, $Y = 0.6h$, $T = 0.425p$, and $R = 0.137p$.

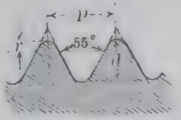

Fig. 8. Whitworth thread.

Either design provides greater cross-sectional area at the root of the thread than the Unified form of thread. Interference between the crest of the internal thread and the tapered flats of the external thread provides a locking and sealing action when assembled. Nuts are Unified and American standard with tap-drilled minor diameters held to limits to insure uniform assembly torque. Lok-Threads are reusable and can replace Unified and American threads. Lead threads are provided for ease of starting.

BRITISH STANDARD WHITWORTH (BSW) threads employ a 55-degree included angle (Fig. 8). Actual depth of the thread is two-thirds the height of the sharp V-thread and is $d = 0.640327p$; radius at crest and root is $r = 0.137329p$, where p = pitch. Diameter and pitch combinations and basic sizes of bolts are listed in Table 20. Effective diameter (equivalent to pitch diameter in American nomenclature) is the mean of the full (major) and the core (minor) diameters. Corresponding dimensions of nuts are greater

by 0.002 Tables of close, medium, and free fits are published in the British Standards Institution *Report* 84-1940

BRITISH STANDARD FINE (BSF) threads are of the same form as the Whitworth (Fig. 8). Diameter and pitch combinations and basic sizes of bolts are listed in Table 21. Corresponding dimensions of nuts are greater by 0.002 in. For sizes above 4 1/4 in., 4 threads per inch are recommended.

BRITISH ASSOCIATION (BA) threads have an included angle of 47 1/2 degrees (Fig. 9). Actual depth of the thread is 0.6p, approximately, and the radius at crest and root is $r = {}^2/_{11}\ p$, approximately. Diameter and pitch combinations and basic sizes are listed in Table 22. The BA thread is recommended by the British Standards Institution for screws below 1/4 in., except the 7/32-in. BSF size, which is recommended in preference to the No. 0 BA size.

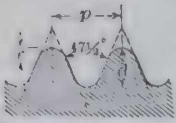

Fig. 9. British Association thread.

INTERNATIONAL STANDARD (SI) metric threads employ a 60-degree included angle and proportions similar to the American National thread. Crests are flat, and roots may be flat or rounded, the exact shape being left to the manufacturer. Depth of engagement is 0.6495p, which is the same as the basic depth of thread form of the American National thread. Crest clearance adds 0.045p (max 0.054p, min 0.036p) to the height, making the actual thread depth 0.7p (max 0.7035p, min 0.6855p). Diameter and pitch combinations and basic sizes of metric threads are listed in Table 23.

TAPS. Standard dimensions and tolerances for cut and ground thread taps are covered by American Standard ASA B5.4-1948. Cut thread taps made to these specifications should, when used under normal conditions, produce holes within class 2 tolerances. Ground thread taps similarly used may be expected to produce holes within class 3 tol-

erances. However, on account of varying conditions, the size of a tapped hole cannot be guaranteed.

The standard includes a list of definitions and tap terminology, from which the following paragraphs are excerpted.

Regular (Standard) Hand Taps. A short tap with thread and shank approximately the same length, the latter having a square to accommodate a tap wrench or other driving mechanism. Made in fractional sizes only. Developed for use by hand but used largely in machines at the present time. Furnished in taper, plug, and bottoming types, the difference being in the number of threads chamfered, as follows: bottoming, 1 to 1 1/2 threads; plug, 2 1/2 to 5 threads; taper, 7 to 9 threads.

Three Fluted Hand Taps. Identical with regular (standard) hand taps except they have a smaller number of flutes. Suitable for machine use in tapping tough stringy metal.

Spiral Pointed Hand Taps. Regular (standard) hand taps having a fewer number of flutes and wider lands; cutting face of the first few threads ground at an angle to force the chips ahead to prevent clogging in the flutes.

Serial Hand Taps. Regular (standard) hand taps in sets of three, No. 1 being smaller than No. 2, and No. 2 smaller than No. 3 in pitch diameter, so that the work is distributed among three taps. For very tough metal where a full thread cannot be cut at one pass. Distinguished by rings on the shank near the square.

Regular (Standard) Machine Screw Taps. Similar to the regular (standard) hand taps except that they are made in so-called numbered or machine screw sizes.

Spiral Pointed Machine Screw Taps. Regular (standard) machine screw taps having fewer flutes, wider lands, and cutting face of the first few threads ground at an angle to force the chips ahead to prevent clogging in the flutes.

Nut Taps. Designed for use of machine shops which tap their own nuts. Customarily the entering threads for approximately 75% of the thread length have a slight taper in both pitch diameter and root diameter to insure tapping a nut with a full thread form. Length overall, length of thread, and length of shank are appreciably longer than on a regular (standard) hand tap.

Straight Shank Tapper Taps. Used by nut manufacturers in tapping nuts in vertical spindle machines. Made 12 or 15 in. long, the nuts being allowed to accumulate on the shank during tapping. Shanks are machined to fit the various spindles in ordinary use. Made in both fractional and machine screw sizes.

Bent Shank Tapper Taps. Designed for use in an automatic tapping machine. Nuts are fed to the tap by a hopper, there being continuous production of the tapped product without stopping or reversing. Made in both fractional and machine screw sizes.

Pulley Taps. Originally designed for tapping set screw holes in the hubs of steel pulleys. Thread length is approximately equal to that of a regular (standard) hand tap; shank is full diameter of thread, in various lengths. Meet demand for hand taps of longer length.

Boiler Taps. Hand taps having 12 threads per inch for use by locomotive builders and railroad shops for tapping holes in boiler plate. Available straight, and tapered ($^3/_4$ in. per ft).

Mud or Washout Taps. A hand tap having $1^1/_4$ in. taper per foot and 12 threads per inch. For tapping and retapping holes in mud drums of boilers.

Staybolt Taps. Have 12 threads per inch and a long shank and reamer section. Used, generally in an air drill, to tap boiler sheets preparatory to inserting staybolts.

Spindle Staybolt Taps. A short tap with a hole drilled through its entire length through which a guide spindle fits. Used for tapping holes from the inside of locomotive fireboxes.

Taper Pipe Taps. A hand tap used for tapping American Standard taper pipe fittings, either by hand or by machine.

Straight Pipe Taps. A hand tap identical with the taper pipe tap but with threaded portion straight and of proper size for tapping American Standard straight pipe thread.

Materials. Cut thread taps may be carbon steel or high-speed steel. Ground thread taps, both commercial and precision ground, are high-speed steel.

TAP DRILLS. Selection of tap drill size depends on the percentage of full thread desired or considered practical from a production standpoint. The percentage is figured on the basic height of the original American National thread form (Fig. 5), which is $h = 0.64952p$ or $0.64952/n$, where n is the number of threads per inch. Basic height of the Unified and American thread form (Fig. 3) for an internal thread is $5H/8$ or $0.54127/n$; hence the percentage of full thread is 0.54127/0.64952 or 83.3%, for a thread pair in the maximum metal condition.

For any thread pair having major diameter of the external thread equal to D and minor diameter of the internal thread K, the actual thread height is $(D - K)/2$. Dividing the actual thread height by the basic thread height, $0.64952/n$, and multiplying by 100 gives the percentage of full thread:

$$T = 77n(D - K) \tag{28}$$

Transposing eq. 28 gives a convenient formula for calculating the size of tapped hole for any desired percentage of full thread:

$$K = D - \frac{T}{77n} \tag{29}$$

Determination of tap drill size may be made by first finding the value of K_n in Tables 3, 4, 5, 6, 7, or 8 if a close approximation to a standard thread is desired, or by calculating K from eq. 29 if some other percentage T is desired. The nearest standard size drill may then be selected, referring to Table 1 in Article 23, Section 23, for numbered, lettered and fractional size drills. If the nearest standard size differs markedly from the desired size, eq. 28 may be used to check the actual percentage of full thread, allowing for accuracy of drilling.

3. BOLTS, NUTS, AND SCREWS

Screw fasteners in commonest use may be broadly classified according to style and application as (1) bolts, (2) studs, (3) cap screws, (4) machine screws, (5) set screws, (6) carriage bolts, and (7) wood screws. Dimensions of the various styles of heads, points, and nuts have been standardized by the ASA and are summarized in Tables 24 to 49 inclusive. For complete details of manufacturing tolerances, the appropriate standard which is identified at the top of each table should be consulted.

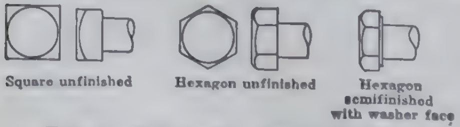

FIG. 10. Bolt heads. See Table 24.

BOLTS, used preferably in through holes with the appropriate nut, are furnished with square or hexagon heads, *unfinished*, *semifinished*, or *finished* (see Fig. 10, and Table 24).

Unfinished Bolt Heads (see Fig. 10 and Table 24) have flat tops and are chamfered to an angle of 25 degrees for square and 30 degrees for hexagon heads, the angle being meas-

2 $^3/_4$	4.1250	1.889	1.744	4.2500	2.181	2.056
3	4.5000	2.060	1.935	4.6250	2.373	2.248

Tolerances on bolt head dimensions are fairly liberal, and the standard should be consulted if actual values of limiting dimensions are needed. Bolt head thickness total tolerances range from approximately $^1/_{32}$ in. for $^1/_4$-in. nominal size to approximately $^9/_{64}$ in. for 4-in. size. Minimum width across flats is 2 $^1/_2$ to 3 $^1/_2$% less than the maximum given. Allowing for slight rounding of corners, width across corners is approximately 1.14 times width across flats for hexagon, and 1.375 times width across flats for square bolt heads and nuts.

ured from the top surface. Diameter of the circle is the maximum width across the flats within a tolerance of minus 15%. Maximum radius under heads is $^1/_{32}$ in. for sizes $^1/_4$ to 1 $^1/_2$ in.; $^1/_{16}$ in. for sizes $^9/_{16}$ to 1 in.; $^1/_8$ in. for sizes 1 $^1/_8$ to 2 in.; and $^3/_{16}$ in. for sizes 2 $^1/_4$ to 3 in.

Semifinished bolt heads are machined or otherwise formed or treated on the bearing surface so as to provide a washer face (Fig. 10). Washer face thickness is approximately $^1/_{64}$ in., included in the head height; diameter is the maximum width across flats within a tolerance of minus 5%. Maximum radius under head and chamfer of top are the same as for unfinished bolt heads.

Finished bolt heads are the same as semifinished except that the surfaces other than the bearing surface are treated to provide a special appearance. The finish desired on all nonbearing surfaces should be specified by the purchaser.

Bolt heads also are classified as *regular* and *heavy series*. Regular bolt heads are for general use. Heavy bolt heads are for use where greater bearing surface is necessary, that is, where a large clearance between the bolt and hole is considered essential. They are also used where greater wrench bearing surface is desired.

Automotive hexagon-head bolts (American Standard) have greater head depth than regular bolts and, in sizes above $^1/_2$ in., less width across flats. Maximum head dimensions are listed in Table 25. For minimum limits the standard should be consulted. Top of the head is flat and chamfered, the angle with the top surface being 30 degrees, and the bearing surface is washer faced (Fig. 10). Threads are either coarse or fine series, class 2A. Minimum thread length (extreme point of bolt to last complete thread) of bolts is $2D + {}^1/_4$ in. for bolts up to and including 6 in. length; and $2D + {}^1/_2$ in. for longer bolts.

Table 25. Automotive Hexagon Head Bolts

(All dimensions in inches)

1/2	.7500	.386	1	1.3125	.768			

Tap bolts are bolts used without a nut in the same manner as a cap screw, a threaded hole being provided in one of the parts to be joined. Their use should be confined to locations where neither a through bolt nor a stud can be used. With soft or brittle materials an insert should be employed, especially if occasional removal is expected.

NUTS, like bolts, are classified as unfinished, semifinished, and finished (see Fig. 11, and Table 26).

Unfinished nuts are threaded only. Semifinished nuts are threaded and finished on the bearing surface either by turning a washer face or by chamfering (Fig. 11). Washer face thickness is 1/64 in., approximately, included in the nut thickness, and diameter is maximum width across flats within a tolerance of minus 5%. Jam nuts (Table 26) are finished on both faces. Tops of nuts are flat and chamfered 30 degrees with the top surface; diameter of top circle is maximum width across flats within a tolerance of minus 15%.

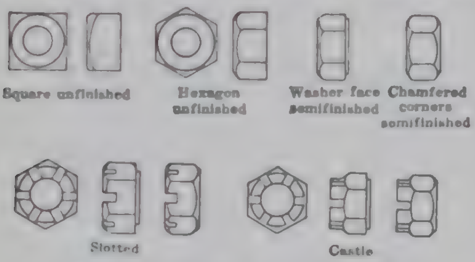

Fig. 11. Nut styles. See Table 26.

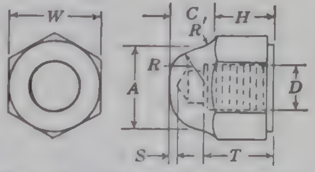

Fig. 12. Cap or acorn nut. See Table 27.

Nuts are furnished in *regular*, *heavy*, and *light series* (Table 26). Regular- and heavy-series nuts are used for the same purposes as the corresponding bolt series. Light-series nuts have smaller dimensions across flats than regular series.

Slotted and castle nuts are illustrated in Fig. 11, standard dimensions being given in Table 26.

Cap, or acorn, nuts are illustrated in Fig. 12. SAE recommended practice for this type of nut is given in Table 27. In addition to the regular and light series, a low-type nut is included. Cap nut construction may be either solid or two piece.

Machine Screw Nuts. Standard dimensions are listed in Table 28. Hexagon machine screw nuts have tops similar to regular series nuts. Bottoms are flat, but for special purposes may be chamfered or washer faced. Square machine screw and stove bolt nuts have tops and bottoms flat without chamfer.

STUD BOLTS. Inasmuch as total lengths and thread lengths are generally determined by the requirements of a particular job, there is no American standard for stud bolts. The following includes recommendations by the Industrial Fasteners Institute.

Tap-end stud bolts are chamfered on the tap end and rounded on the nut end. Length of thread on tap end = $D + 1/8$ in., measured from the end of the stud to the end of the imperfect thread, which should not exceed 2 1/2 threads. Minimum length of thread on nut end = $2D + 1/4$ in. Length of unthreaded portion or shoulder = D except for stud bolts shorter than $4D + 3/8$ in., in which case shoulder length may be decreased or eliminated. For very short studs the bolt end thread length may be reduced, but not the tap end.

Thread fit in the tapped hole is wrench-tight, the preferred method of assembly being to depend on thread tightness to hold the stud, rather than to allow jamming at the imperfect threads or at the bottom of the tapped hole. The patented Lok-Thred provides interference at the minor diameter and is used for studs in certain applications. Inserts ranging

Tolerances on nut dimensions are fairly liberal, and the standard should be consulted if actual values of limiting dimensions are needed. Nut thickness total tolerances range from approximately 1/32 in. for 1/4-in. nominal size to approximately 9/64 in. for 4-in. size. Minimum width across flats is 2 1/2 to 3 1/2% less than the maximum given. Allowing for slight rounding of corners, width across corners is approximately 1.14 times width across flats for hexagon, and 1.375 times width across flats for square nuts.

For limiting dimensions, the standard should be consulted. Nut thickness total tolerances range from 0.007 in. for No. 0 size to 0.018 in. for 3/8 in. size. Minimum width across flats is approximately 3 to 4% less than the maximum.

from simple threaded bushings through a variety of patented designs are often used with softer materials, especially where occasional removal of the stud is anticipated. With soft materials such as aluminum the thread on the tap end is sometimes larger and coarser than that on the bolt end.

Double-end stud bolts (rod) are symmetrical, both ends having rounded points and thread length $2D$ + 1/4 in., measured from the end of the stud to the end of the imperfect thread, which should not exceed 2 1/2 threads. Threads may be rolled or cut.

Continuous thread stud bolts (flange studs) are chamfered at both ends and have a continuous thread from end to end.

WRENCH OPENINGS for standard bolts and nuts are listed in Table 29. The minimum wrench openings provide a positive clearance between maximum nut and minimum wrench opening. The plus tolerance is as great as possible without danger of deforming the hexagon corners under extreme conditions.

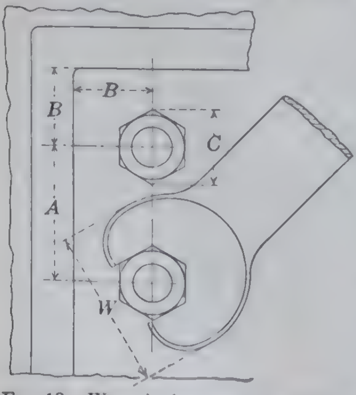

FIG. 13. Wrench clearance dimensions.

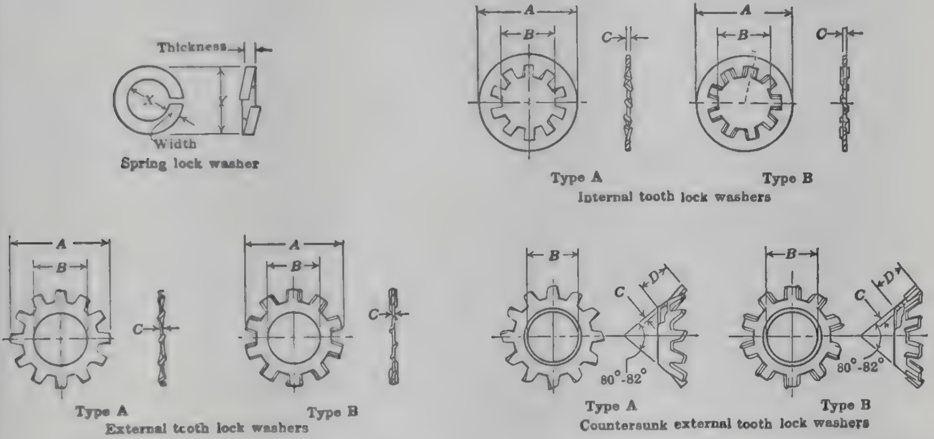
Bolt Spacing for Wrench Clearance. Space between bolts, and between bolts and adjacent projections, may be estimated from these formulas, given in *Machinery's Handbook* (see Fig. 13 for notation):

$$A = 1/2\,(W + C + d) \qquad B = 0.48W$$

where *d* is the nominal bolt diameter. Value of *C*, the distance across the corners of the nut or bolt head, is approximately 1.14 times the distance across the flats, which may be obtained from Tables 24, 25, 26, 27, or 28. Maximum width of wrench head, *W*, may be obtained from Table 30.

WASHERS. Dimensions of standard plain washers for general industrial purposes are listed in Table 31. They include light, medium, heavy, and extra heavy series washers in a composite listing.



Spring lock washer

Type A Type B
Internal tooth lock washers

Type A Type B
External tooth lock washers

Type A Type B
Countersunk external tooth lock washers

FIG. 14. Lock washers. See Tables 32 and 33.

Spring lock washers, illustrated in Fig. 14, have standard dimensions listed in Table 32. Spring lock washers are made from carbon steel fabricated and treated to a hardness of 45 to 53 Rockwell C.

Tooth lock washers are illustrated in Fig. 14, and their leading dimensions are listed in Table 33. The number of teeth, length of teeth, width of rim, and thickness of washer

13/32	13/16	.080	.051	15/16	2 1/4	.192	.136				

Diameter tolerances are ±0.010-in., except the ID tolerances on 5/64 to 7/32 in., and 1/4 in. where OD is 9/16 in., which are ±0.005 in.

Thicknesses are Birmingham gage. Limits given represent tolerance of plus or minus one gage, or the spread from the minimum of one gage minus to the maximum of one gage plus.

* Thickness tabulated is the nominal mean thickness of the trapezoidal section, that is, $(T + t)/2$, where T is the thickness at the inner periphery and t the thickness at the outer periphery (Fig. 14). T is larger than t by an amount ranging between $0.032W$ and $0.064W$.

over the teeth (free height) are optional with the manufacturer. Washers are carbon steel fabricated and heat treated to a hardness of 40 to 50 Rockwell C.

INTERNAL WRENCHING BOLTS. High-strength, high-temperature internal wrenching bolts have cylindrical heads with hexagon sockets (Fig. 15). Leading dimensions are listed in Table 34. Length, L, increases by $^1/_8$-in. increments up to 1 in., by $^1/_4$-in. increments over 1 in. to 4 in., and by $^1/_2$-in. increments over 4 in. in length. Thread tolerances conform to ASA class 7 (see Table 18), and the internal mating threads should conform to class 2 tolerances (see Table 13). The heads are larger than those of socket head cap screws (Fig. 17) to provide greater bearing surface under the head and to insure head and wrench strength.

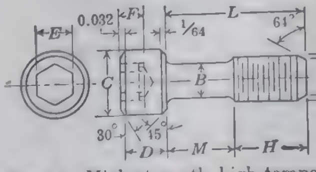

Fig. 15. High-strength, high-temperature internal wrenching bolt. See Table 34.

MACHINE SCREWS. Figure 16 illustrates the various types of machine screws standardized by the ASA. Tables 35, 36 and 37, list their leading dimensions. For details of specification and manufacturing tolerances the standard (ASA B18.6-1947) should be consulted. Referring to the designation of machine screws by number, it is convenient

Edges of head on flat- and oval-head machine screws may be rounded.

Radius of fillet at base of flat- and oval-head machine screws shall not exceed twice the pitch of the screw thread.

Radius of fillet at base of round- and fillister-head machine screws shall not exceed one-half the pitch of the screw thread.

All four types of screws in this table may be furnished with cross-recessed heads of either style shown in Fig. 15.

Fillister-head machine screws in sizes No. 2 to 3/8-in., inclusive, may be furnished with a drilled hole through the head along a diameter at right angles to the slot but not breaking through the slot.

Table 36. Dimensions of American Standard Machine Screw Heads—Pan, Hexagon, Truss, and 100-degree Flat Heads

(ASA B18.6-1947. All dimensions in inches. See Fig. 16.)

Radius of fillet at base of truss- and pan-head machine screws shall not exceed one-half the pitch of the screw thread.

Truss-, pan-, and 100-degree flat-head machine screws may be furnished with cross-recessed heads of either style shown in Fig. 15.

Hexagon-head machine screws are usually not slotted; the slot is optional. Also optional is an upset head type for hexagon-head machine screws of sizes 4, 5, 8, 12, and 1/4 in.

Table 37. Dimensions of American Standard Machine Screw Heads—Binding Head

(ASA B18.6-1947. All dimensions in inches. See Fig. 16.)

5/16	.3125	.641	.193	.072	.112	.077	.450	.027
3/8	.375	.769	.234	.081	.136	.094	.540	.034

Binding-head machine screws may be furnished with cross-recessed heads of either style shown in Fig. 16.

* Use of undercut is optional.

to note that a No. 5 screw has a major diameter 1/8 in. (0.125) and that the difference in diameter between successive numbers is 0.013 in.

Machine screws are regularly supplied with plain sheared ends, not pointed (Fig. 16). Header points with included angle of chamfer 40 to 45 degrees are obtainable up to certain lengths. On machine screws up to 2 in. long, complete threads extend to within two threads of the bearing surface of the head; longer screws have minimum complete thread length $l = 1\frac{3}{4}$ in. Diameter of the unthreaded portion of machine screws is not less than the minimum pitch diameter or more than the maximum major diameter of the thread.

Screw threads on machine screws are Unified or American National Coarse or Fine thread series, class 2 or 2A. They are regularly supplied with a naturally bright finish, not heat treated.

Machine Screw Heads. With the exception of the hexagon, all heads illustrated in Fig. 16 may be obtained with a screwdriver slot, as shown, or with one of the two styles of cross recess illustrated. The "clutch head" style shown is available commercially. Slot dimensions are included in Tables 35, 36 and 37; for cross-recess dimensions the standard should be consulted. Complete details of cross recesses and drivers may be obtained from manufacturers licensed to produce them.

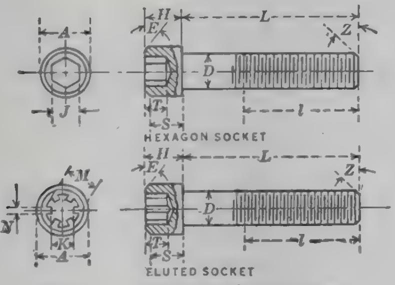

FIG. 17. Socket-head cap screws.

Binding-head screws (Table 37) are usually undercut as shown in Fig. 16, but the undercut is optional.

CAP SCREWS (Figs. 16 and 17) have chamfered points. Leading dimensions are listed in Tables 38, 39 and 40. For details of specification and manufacturing tolerances, the appropriate standards should be consulted.

Table 38. Dimensions of American Standard Slotted-head Cap Screws

(ASA B18.6-1947. All dimensions in inches. See Fig. 16.)

Nominal Size (Body Diameter, max), *D*	Width of Slot, min, *J*	Fillister Head				Flat Head			Round Head

7/8	.147	1.125	.594	.720	.264	1.625	.423	.139	.....	.....	.....
1	.166	1.312	.656	.802	.292	1.875	.494	.162			

For fillister- and round-head cap screws, radius of fillet at base of head is 0.016 to 0.031 in. for sizes 1/4 to 3/8 in., incl.; 0.016 to 0.047 in. for sizes 7/16 to 9/16 in., incl.; 0.031 to 0.062 in. for sizes 5/8 to 1 in., incl.

For flat-head cap screws the radius of the fillet at the base of the head shall not exceed twice the pitch of the screw thread.

* Maximum socket depth (*T*, Fig. 17) should not exceed three-fourths of minimum head height (*H*).

Head chamfer angle *Z* (Fig. 17) is 28 to 32 degrees, the edge between flat and chamfer being slightly rounded.

Screw point chamfer angle *Z* (Fig. 17) is 35 to 40 degrees, the chamfer extending to the bottom of the thread. Edge between flat and chamfer is slightly rounded.

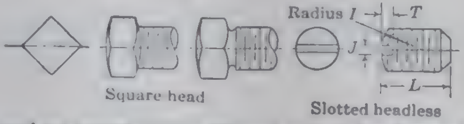

FIG. 18. Square-head set screws (Table 40) and slotted, headless set screws (Table 41).

Table 40. Dimensions of American Standard Hexagon-head Cap Screws and Square-head Set Screws

Threads on cap screws are Unified or American National Coarse or Fine series.

Slotted-head cap screws are available in flat, fillister, and round head styles (Fig. 16 and Table 38). Minimum thread length is $2D + 1/4$ in. with a plus tolerance of 2 1/2 times the pitch. When too short for the specified minimum thread length, cap screws have complete threads extending within 2 1/2 threads of the head.

Chamfered points have 90-degree included angle; maximum diameter of the point is 91.5% of the basic minor diameter plus 0.001 in.; minimum is 83.5% of basic minor diameter minus 0.001 in.

Socket-head cap screws are available with hexagon or fluted sockets (Table 39). For dimensions of keys fitting these screws, the standard (ASA B18.3-1947) should be consulted. Minimum thread length for coarse threads is $l = 2D + 1/2$ in. or $1/2L$, whichever is greater. Thread length for fine threads is $l = 1\,1/2D + 1/2$ in. or $3/8L$, whichever is greater. Screws too short to allow application of the formulas are threaded as close to the head as practicable.

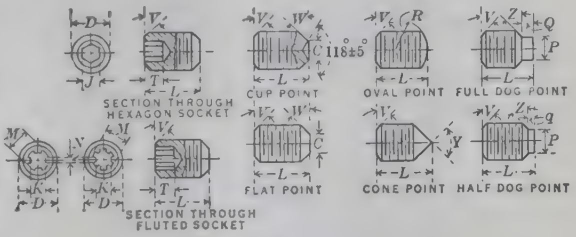

Fig. 19. Headless, socket set screws.

Screw points are flat and chamfered to an angle of 35 to 40 degrees with the flat. Chamfer extends to the bottom of the thread, and edge between flat and chamfer is slightly rounded.

Hexagon-head cap screws (Table 40) have heads with a washer face (see Fig. 10) and

Chamfers and point angles are (see Fig. 19):

$W = 45$ to 50 degrees

$Y = 116$ to 120 degrees when L equals or is less than the nominal diameter

$Y = 88$ to 92 degrees when L is greater than the nominal diameter

$Z = 35$ to 40 degrees

$V = 35$ to 40 degrees

Number of flutes is 4 for sizes 5 and 6. All other sizes have 6 flutes.

are usually finished all over. Length of thread is $2D + 1/4$ in., minimum thread length being measured from the end of the screw to the last complete thread.

SET SCREWS are made with square heads, or headless with a slot for a screwdriver (Fig. 18), or with a socket into which a key can be inserted (Fig. 19).

surface of the head is beveled not more than 40 degrees, and the top or crown of the head is rounded to a radius 2 1/2 times the major diameter of the thread. Point styles are illustrated in Fig. 19, point dimensions being given in Table 41.

Headless set screws are threaded the entire length. Screw threads are Unified or American National Coarse or Fine series, class 2 or 2A, unless otherwise specified. Standard dimensions are listed in Table 41, and the various styles are illustrated in Figs. 18 and 19. When the usable length of thread is less than the nominal diameter, the half-dog point is used. Slotted-type set screws are regularly furnished case hardened.

Dimensions of keys for hexagon and fluted sockets may be found in the standard, ASA B18.3-1947.

CARRIAGE BOLTS, used where the head bears against wood, are illustrated in Fig. 20. Leading dimensions are given in Tables 42 and 43. Screw threads conform to the Unified or American National Coarse thread series and may be either cut or rolled. Leading dimensions of countersunk, button head, and step bolts are given in Table 44 and the styles are illustrated in Fig. 21.

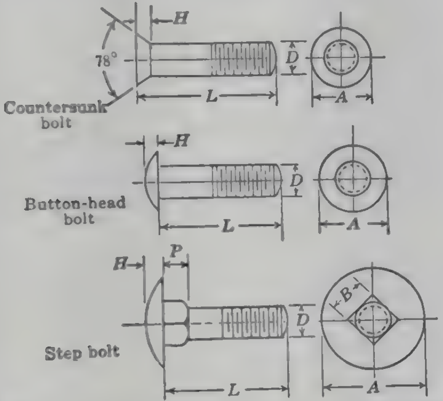

FIG. 21. Countersunk, button-head, and step bolts. See Table 44.

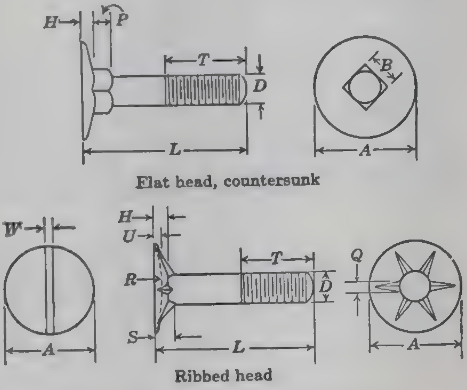

FIG. 22. Elevator bolts. See Table 45.

ELEVATOR BOLTS are illustrated in Fig. 22, and leading dimensions are given in Table 45. The oval-head elevator bolt, or step bolt, is illustrated in Fig. 21, dimensions being given in Table 44.

* In order to make the edge as thin as possible, the circumference of the head may be somewhat irregular.

† Heads may be slotted or unslotted, as specified. Radius of slot, *R*, is 1 1/2 in. (See Fig. 22).

PLOW BOLTS. Two types, the No. 3 and the No. 7, illustrated in Fig. 23, are recommended for new designs. Other types are included in the new American standard. The No. 3 has an 80-degree round countersunk head and a square neck. It is economical to produce and use but is not well suited to application in thin materials; the square weakens the bolted part more than a round hole, making it less desirable for use close to an edge. The No. 7 has a 60-degree round countersunk head and a reverse key. It can be used in thinner sections than the No. 3. Threads are UNC or NC class 2A. Dimensions of regular-head plow bolts No. 3 and No. 7 are given in Table 46; repair head bolts have head dimensions, in general, slightly less than the regular head.

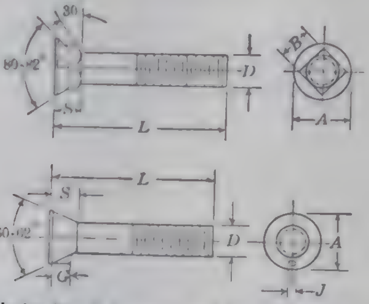

FIG. 23. Plow bolts No. 3 (upper) and No. 7 (lower). See Table 46.

* Dimensions in table are for regular heads. Repair head dimensions are given in the standard.

† This size not recommended.

SHOULDER SCREWS, used as pivots for oscillating or rotating parts, are illustrated in Fig. 24. Leading dimensions of socket-head shoulder screws are listed in Table 47.

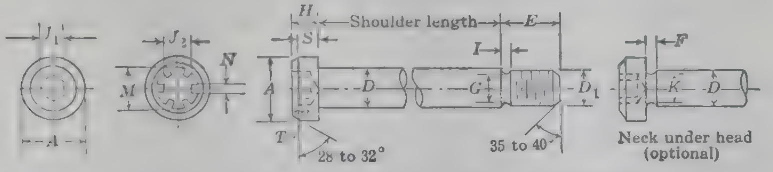

FIG. 24. Shoulder screws (stripper bolts). See Table 47.

T BOLTS. Standard dimensions of T bolts, T slots, and nuts are listed in Table 48 and illustrated in Fig. 25. Screw threads on T bolts and studs usually are Unified or American coarse series, class 3 or 2A. The standard for T slots (ASA B5.1-1941) should be consulted for the dimensions of T-slot cutters and of inserted tongues and tongue seats.

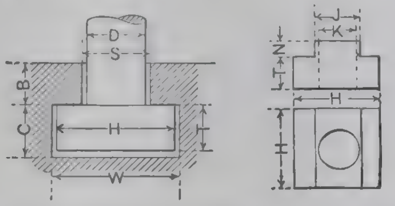

FIG. 25. T-slot bolts and nuts. See Table 48.

TAPPING SCREWS are of three types (Fig. 26 and Table 49). Length of tapping

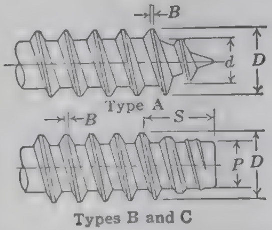

FIG. 26. Tapping screws. See Table 49.

screws is measured from the largest diameter of the bearing surface of the head to the extreme point. All types are threaded to the head and are regularly furnished case hardened. Tapping screws are available with heads of the following types: truss, pan, round, flat, oval, and hexagon (see Fig. 16).

4. LOCKING FASTENERS

A nut and bolt properly tightened will not loosen provided sufficient pressure is maintained between the threads and at the nut and bolt-head seats. Under vibrating loads these pressures may be periodically relieved, permitting the nut or screw to loosen. Because so many machinery applications involve vibration a wide demand for locking fasteners exists. Many commercial fasteners are now available, with new ones continually being developed, and no attempt will be made to cover all types. A few general locking methods will be discussed, the principles employed in classifying locking fasteners will be outlined, and brief mention will be made of some of the more widely used commercial fasteners available in 1949. For latest information on locking fasteners the reader is referred to current technical periodicals and to manufacturers' catalogs.

COTTER PINS secured in holes drilled in the bolts, with either plain or castle nuts (see Table 26, p. 10-35), positively prevent the fastener assembly from falling apart, and are widely used in the interior of machines such as engines, where complete separation of fastener elements could have disastrous results. The method is not well adapted to quick assembly and does not necessarily prevent relaxation (loss of bolt tension).

WIRES threaded through holes drilled in the heads of two or more cap screws serve the same purpose as cotter pins with nuts, preventing the screw from falling out or turning more than a few degrees but not necessarily preventing relaxation.

LOCKING PLATES attached to the bolted part and bearing against the nut or bolt head also are employed to prevent turning.

JAM NUTS used in pairs or in conjunction with plain nuts (see Table 26, p. 10-35) develop internal "locked-up" stresses when tightened against each other, furnishing the necessary pressure against the threads regardless of bolt load. Load is carried by the outer nut.

LOCK WASHERS (Fig. 14, p. 10-37) provide spring take up to compensate for developed looseness between component parts of an assembly. *Spring lock washers* (Table 32) also serve as hardened thrust bearings to facilitate assembly and disassembly by decreasing the frictional resistance between the bolted surface and the bearing face of the bolt head or nut. *Tooth lock washers* (Table 33) provide increased friction between fasteners and assembly.

Lock Washer and Machine Screw Assemblies. For mass production and other operations where speed and convenience are paramount factors, lock washers are assembled permanently to machine screws. The inside diameter of the washers are of a size to permit free rotation but to prevent their coming off the screw after the thread has been rolled. Spring lock washers are standardized in association with pan, fillister, truss, round, and hexagon head machine screws (Fig. 16, p. 10-40). Tooth lock washers are standardized in association with flat, oval, pan, truss, round, and hexagon head machine screws.

LOCKNUTS are of many and varied designs, which have been classified by the Industrial Fasteners Institute. The *tension* class develops at least normal tension load unaided, whereas the *shear* class does not.

Each of these classifications can be further subdivided into *load-locking* and *self-locking* types. The load-locking type requires a base load to develop locking whereas the self-locking type locks whether or not it engages a bearing surface.

Load-locking types in turn may be termed *compression lock* when the locking is due to elastic action which unlocks when the base load is removed, or *bearing set* when the locking is due to permanent deformation which maintains locking even after the base load is removed.

Self-locking types in turn can be *inherent*, requiring a single assembly operation consisting of wrenching to position, or *manual*, requiring multiple assembly operation.

Of the locknuts commercially available in 1949, the following are representative.

Anco-Nut (Automatic Nut Co., Inc., Lebanon, Pa.). This nut has a locking pin that impinges at an angle against the bolt at the base of the threads. This impingement acts in a similar manner to a ratchet, permitting tightening by a wrench but resisting loosening of the nut. Reverse wrenching changes the angle of impingement and permits removal of the nut.

An-cor-lox (An-cor-lox Division of Laminated Shim Co., Glenbrook, Conn.). This nut uses a relatively soft, nonspringing metal ring at the base of the nut to provide locking action. Normally made of bronze, the ring is permanently inserted and is an integral part of the nut. When torque is applied, the ring is flattened and forced into the thread of the bolt.

Bellows (Boots Aircraft Nut Corp., Stamford, Conn.). This is a spring-type locknut in which the locking and load sections are integral. Material is aluminum or Duronze. The bolt threads establish spring tension in the locking section, resulting in a differential thrust in the fastener against the bolt.

Drake (The National Screw and Manufacturing Co., Cleveland, Ohio). This wedge-type fastener is composed of two pieces, a prime nut or lower member which tightens the work to the exact adjustment required, and a locking member which is applied by a firm wrenching action. Contact between the two members takes place on mating tapered sections, the locking member having a male taper extending into the lower member. Each member turns freely on the bolt until seated or locked in position.

Dynamic (The National Screw and Manufacturing Co., Cleveland, Ohio). A groove in the top of this nut and a recess in its base provide a resilient central section which acts as a diaphragm. When the nut is tightened to the adjustment desired, an outward axial spring action develops. This tension in the upper diaphragm causes a constant pressure on the upper flanks of the nut threads and the mating lower flanks of the bolt threads, locking them together.

Esna (Elastic Stop Nut Corporation of America, Union, N. J.). Locking element in this reusable, interference-type nut is a nonmetallic compression collar locked into the head of the nut. The nut is made so that the center opening of the compression collar is somewhat smaller than the bolt, thus giving a friction grip on the threads of the bolt.

Flexloc (Standard Pressed Steel Co., Jenkintown, Pa.). Top of this one-piece, all-metal, reusable-type stop nut has six radial slots which provide six resilient sections to do the actual locking. Pressure due to deflecting these sections creates a firm grip on the bolt threads.

Gripco (Grip Nut Co., Chicago, Ill.). Three triangular depressions on one face of the one-piece nut deform the adjacent threads so as to cause pressure on the bolt threads. The resulting friction locks the nut on the bolt. Nut is reusable.

Huglock (National Machine Products Co., Detroit, Mich.). This one-piece, reusable, all-metal locknut is formed with a slotted tapered top and is threaded the full length of the nut. The slotted portions are curved in so that the six tapered segments press inwardly against the bolt, creating a friction lock.

Lamson (The Lamson and Sessions Co., Cleveland, Ohio). This one-piece, reusable, spring stopnut has a collar on top and is threaded in the usual way. The locking collar is distorted from the round on opposite sides, causing it to grip the bolt threads when assembled. Permanent spring action is given the collar by heat treatment.

Loktite (Lewis Bolt and Nut Co., Minneapolis, Minn.). A curved arch on the bearing face of this nut flattens as the nut starts to bear. This causes the thread to become deformed, creating frictional tension and spring action which locks the engaging threads of the bolt and nut.

Marsden (American Marsden Co.). Upper portion of this one-piece, reusable nut is slotted, forming six threaded segments, and the bottom face is recessed so that a continuous seating surface is provided outside the thread pitch line. When the nut is tightened to a seat, the threaded upper segments move radially inward, causing the nut threads to align themselves securely with their mating bolt threads, and producing a friction lock.

M-F Lock Nut No. 1 (MacLean-Fogg Lock Nut Co., Chicago, Ill.). Applied over a common nut to hold it in place, this is a free-spinning, seating-lock, reusable-type fastener. The nut takes a permanent set and must be wrenched for further movement. Both faces of the nut are arched (concave). When the arched surface contacts the top of the common nut and flattens due to additional tightening, the nut threads are deflected and bind against the bolt.

M-F Speed Holding Nut No. 2 (MacLean-Fogg Lock Nut Co., Chicago, Ill.). Lower surface of this nut is arched (concave), and the upper half has a wide recess extending across the nut and approximately half way through the thickness. When the lower arched face is flattened by tightening against the face of the work, the top portion deflects inward, binding the nut threads against the bolt threads. The nut is used alone and can be applied to bolts which cannot be held against rotation.

M-F Unitary Nut No. 3 (MacLean-Fogg Lock Nut Co., Chicago, Ill.). The top two or three threads of this reusable-type lock nut are deflected slightly out of the true helix. The nut starts freely on the bolt but requires wrenching to final position, the induced friction at the distorted threads clamping the nut in place. The nut is used alone.

Nylok (Nylok Corp., New York, N. Y.). Two types of self-locking torque nuts are available: the E type has a nylon plug through one of the hexagon sides acting as a wedge; the N series has on top an annular nylon insert which is slightly undersize, causing lateral pressure and friction against the bolt.

Palnut (the Palnut Co., Irvington, N. J.). This is a single-thread spring steel locknut usually formed in a hexagon shape to standard nut dimensions. The formed sides are turned up to provide wrench-engaging surfaces, and the hole is spirally formed to engage the bolt thread. When wrench tightened, the inner section yields with spring forces reacting downward on the work surface, upward on the bolt thread, and inward on the root of the bolt thread, resulting in secure locking action.

Roltop (Boots Aircraft Nut Corp., Stamford, Conn.). This one-piece, reusable, spring-type locknut has a resilient locking section at the top which eliminates axial thread play. Spring tension established in the locking section results in downward thrust by the nut threads of the locking section against the bolt threads, and upward pressure of the nut threads in the load section against the bolt threads.

Speed Nut (Tinnerman Products, Inc., Cleveland, Ohio). This reusable, seating-lock type fastener is made of flat spring steel with an arched base and two arched prongs which engage the bolt threads. As the nut is tightened, the two arched prongs are forced down and inward to engage and lock against the root of the screw thread. In addition, the compression of the arch in both prongs and base gives a strong upward thrust against the screw threads.

Stover (Stover Lock Nut and Machinery Corp., Easton, Pa.). The locking characteristics of this reusable, one-piece, spring-type nut are obtained by compressing two opposite flats of the nut so that the top becomes elliptical in shape while the bottom remains circular. The elliptical section provides a heavy spring grip on two opposite sides of the bolt.

Tri-Lok (Boots Aircraft Nut Corp., Stamford, Conn.). Locking action of this spring-type nut is achieved by radial compression at three points at the top of the nut, by shearing the nut walls. A slight downward out-of-phase set is also established in the shearing operation.

Wing Nut (Boots Aircraft Nut Corp., Stamford, Conn.). Made of sheet metal (steel and aluminum), these nuts are designed primarily for weight saving. Their action is similar to that of the Bellows and Roltop locknuts.

SELF-LOCKING THREADS. Dardelet and Lok-Thred threads (see p. 10-29) lock by wedging action of tapered surfaces at the crest of the nut threads and root of the bolt threads. Dardelet is a load-locking type, and Lok-Thred a self-locking. Both are reusable.

5. STRENGTH OF SCREW FASTENERS

By William G. Waltermire

STRENGTH OF THREADED ASSEMBLY. Where both elements of the assembly are of the same material, the screw or bolt will fail by breaking or stripping when loaded to failure. The ultimate load of the screw or bolt, therefore, becomes the proof load of the nut. The proof load of the bolt or screw is based on the yield strength of its material. Table 50 shows recommended classes of bolt and nut material. All values are based on the stress area listed in Tables 3, 4, 5, 6, 7, and 8. This is the area at the mean of the pitch and minor diameters.

Table 50. Grades of Bolts

(From SAE Recommended Practice)

	Minimum Tensile, psi	Elastic Proof Load, psi	Brinell	Rockwell
Commercial bolts	55,000	....	207 max	95 B max

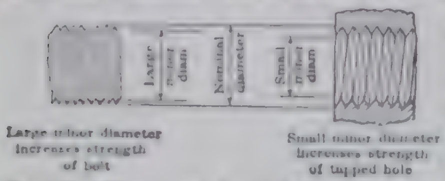
Over 1 to 1 1/2 in., incl.	105,000	74,000	223–285	19–30C
Medium-carbon Alloy, Quenched and Tempered				
1/2 in. and under	150,000	120,000	302–352	32–38C
Over 1/2 to 1 in., incl.	140,000	110,000	285–352	30–38C
Over 1 to 1 1/2 in., incl.	125,000	95,000	255–321	25–34C

Note: Nuts must meet minimum tensile requirements of bolts.

The action of the threads in engagement accounts for the ability of a nut to fail a bolt of the same material. As a result, nut material with a lower modulus of elasticity than the bolt may be used and is recommended. This permits the threads in the nut to conform more readily to the bolt threads and maintains more uniform contact pressure, thus raising the fatigue strength of the bolt.

SELECTION OF THREAD CLASS AND FIT. As illustrated in Fig. 27, when the externally threaded part of a joint is the weakest, as is generally the case with a bolt and nut, a fine thread will develop the greatest static tensile strength. However, where, as is often the case, the material around the tapped hole is the weakest, a coarse thread will develop the greatest static strength of the joint.



Large minor diam
Nominal diameter
Small minor diam
Large minor diameter increases strength of bolt
Small minor diameter increases strength of tapped hole

Fig. 27. Fine-thread bolt (left) and coarse-thread tapped hole (right).

It is generally agreed that coarse threads develop at least as high a fatigue strength under highly stressed vibratory loading as fine threads. A loaded nut dilates at the bottom and compresses axially, thus reducing the pitch. At the same time the bolt contracts radially and stretches, thus increasing its pitch. This action is accompanied by flexion of the triangular section of the threads. The result produces a progressive decrease of the unit load on the threads until the top thread carries proportionally less of the average load per thread.

As a result of this action, some authorities caution about the use of the relatively shallow fine-thread series on large-size bolts and screws, as the threads are more readily disengaged by the "breathing" action of the joint.

It is now generally agreed that a close thread fit does not improve the strength of a joint or its resistance to loosening under loading. On the other hand, it increases the danger of metal interference due to chips or burrs, plating, and heat of driving.

EFFECT OF FASTENER DESIGN AND LOCATION ON STRENGTH. The strength of a screw or bolt in tension is determined by its smallest cross-sectional area, which, on conventional bolts, is in the threads. Hence the unit stress is higher and the consequent deformation is higher than in other portions. If the unit stress in the body of the bolt or screw is made equal to that in the threaded portion, the deformation will be uniform throughout the whole length and its capacity to meet shock loads within the limits of elasticity of the fastener will be correspondingly increased. This may be done by using a bolt of reduced body diameter, as indicated in Fig. 28 or a Place bolt as shown in Fig. 29. The latter has a hollow head and a counterbored bearing face so proportioned that they provide a highly resilient head which is still stronger than the body of the bolt.

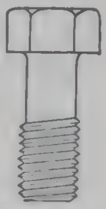


Fig. 28. Bolt of reduced body diameter for increased shock resistance.

Increasing the thread length increases fatigue life and may be used in lieu of reducing the body diameter as long as the fastener does not function in shear. Any of these means increase the total stretch in the bolt and hence make it more resistant to loosening.

While the nut could be redesigned to accomplish the same end, using tapered threads, annular notches around the bearing face, or other means, cost considerations for one make it generally inadvisable.

For best results the angle of thread runout should be 15 degrees or less (30-degree included angle), and the radius at the root of the threads ought to be rounded. Commercial roll-threaded bolts and screws normally have rounded roots.

For a given material, it has been found that screws with threads rolled on after heat treatment have a much higher fatigue strength than screws with cut threads or with threads rolled on before heat treatment. In other words, heat treatment will not increase the fatigue strength of threaded parts.

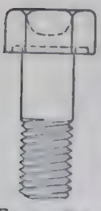

Fig. 29. Place bolt.

In Figs. 30, 31, and 32, J. O. Almen (Ref. 1) illustrates the effect of elastic elements in a design on strength. Good design requires the maximum stiffness of the bolted material and the maximum elasticity of the bolt.

Bruno and Schmittner (Ref. 2) studied the effect on loading of two steam chests, whose walls were located relative to the bolt or stud centerlines, as shown in Fig. 33. They found that, as the wall was brought out with respect to the bolt or stud centerline, the moment caused by the load, tending to open the joint at the flange, diminished and then reversed in sign; and the tests bore this out. No leakage was found with the wall positioned as shown at *C*.

SHEAR LOAD. If the load applied to the screw or bolt in service produces a shearing action, the shank should be full size so as to fit the hole as accurately as practicable and, where P is the load per fastener, d, the fastener diameter, and S_s, the shearing stress, $p = (\pi/4)d^2S_s$ and $S_s = 4p/\pi d^2$.

The clamping force induced by adequate prestress, according to F. B. Frankland (Ref. 3) will account for as much as 15% increase in resistance to shear, although this is not taken into account by conventional design methods.

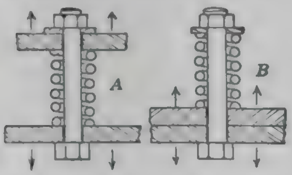

FIG. 30. Effect of design on bolt strength. In *A*, spring is part of abutments and bolt is weak. In *B*, spring is part of bolt, and bolt is strong. (Reproduced by permission from Tightening Is Vital Factor in Bolt Endurance, by J. O. Almen, in *Machine Design*, Feb. 1944)

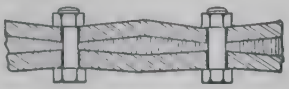

FIG. 31. Elastically deformed plates and gasket increase maximum and cyclic bolt loads. (Reproduced by permission from *Machine Design, loc. cit.*)

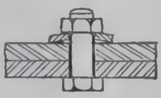

FIG. 32. Spring washer can augment bolt elasticity, resulting in longer bolt life. (Reproduced by permission from *Machine Design, loc. cit.*)

BENDING STRESSES. The effect of bending in increasing the combined stresses in a fastener, thus reducing the useful tensile stress it can develop, has long been recognized. Bending can be caused by actual bend in the bolt, runout (eccentricity) of a screw used in a tapped hole, or by angularity between the face of a bolt head or nut and their mating surface. The latter condition was demonstrated by Bruno and Schmittner (Ref. 2) in the case of a $^7/_8$-in. nut which had 0.015-in. clearance at one side when the nut was finger-tight. Curve *A* (Fig. 34) is for a nut which was apparently true with its mating surface. Curve *B* was for a nut with 0.015-in. clearance at one side.

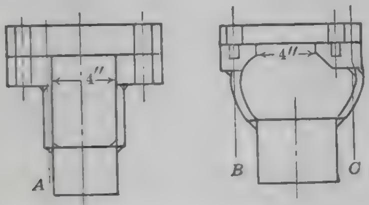

FIG. 33. Steam chests with wall center line (*A*) inside bolt center line, (*B*) in line with bolt center line, and (*C*) outside bolt center line. (Reproduced by permission from Studies on the Bolting of a Fabricated Steam Chest, by Bruno and Schmittner, in *Fasteners*, Vol. 4, No. 2)

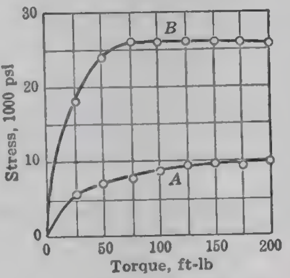

FIG. 34. Stress in a 7/8-in. bolt having a nut (*A*) true with its mating surface and (*B*) with a 0.015-in. clearance at one side. (Reproduced by permission from *Fasteners, loc. cit.*)

The term *runout* includes eccentricity of the thread and shank, bend and out of roundness. It is particularly important on cap screws and fasteners used in tapped holes. The automobile industry has generally adopted a sleeve gage, as shown in Fig. 35, to control runout. The internal diameter of the sleeve gage is opened to equal the maximum body diameter plus the runout allowance. At the end of the gage a thread ring gage, set to basic pitch diameter and centered by a setting plug, is located. Standard runout allowance for cap screws is 0.010 in. per inch of screw length.

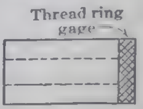

FIG. 35. Runout gage.

PRESTRESSING. In the left view of Fig. 36 the fastener is shown as having a spring body for purposes of the illustration, and the bolted material *B* is assumed to be rigid. It is obvious, therefore, that when the nut is tightened, a load is induced under the nut at *X* and at the face of the joint at *Y* that is due to stretching the spring (bolt). Furthermore, if an external load is applied at *A* as shown, it will not move the assembly, that is, further stretch the spring (bolt) until it is at least as great as the induced load. For example, if *Y* is 2000 lb any external load less than 2000 lb would not stretch the spring.

The latter would be stretched as the load exceeded 2000 lb. Thus, prestressing provides freedom from vibration within certain limits.

In the right side of Fig. 36 the conditions of relative stiffness are reversed. The bolt is shown as rigid, and the bolted material, *B*, is represented by a spring. In this case it is obvious that screwing up the nut will not provide the same immunity to vibration as before, but that instead much of the prestress will be additive to the external load. This condition is approached when the joint is relatively less stiff than the fastener owing to its material or to the use of gaskets, springs, or resilient sealing materials.

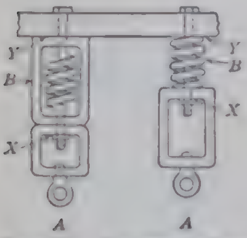

Fig. 36. Representation of resilient bolt with stiff connected parts (*left*), and a stiff bolt with resilient parts (*right*).

These situations represent the two extremes. Kimball and Barr (Ref. 4) suggest that the following be used as limiting guides in deciding the proportion the initial load or prestress ought to bear to the external load. The combined load, of course, cannot exceed the rated proof stress of the bolt or screw.

1. If a bolt is manifestly very much more yielding than the connected members, design the bolt simply for the initial load or for the external load, whichever is greater.
2. In case of extreme yielding of the connected members, assume the resultant load to be nearly the sum of the initial and external loads.

AMOUNT OF PRESTRESS. Most of the ordinary usages fall in condition 1 above. The author recommends in this case that the prestress be limited to 80% of the value of the proof strength. This is to allow for some addition of external load, for errors and variations in driver torques, for uncontrolled variations in frictional conditions of driving, and other conditions affecting stress and torque. It has been found that when bolts fail during driving (Ref. 5) they fail at induced tensions as low as 68% of the rated tensile strength. If driven just short of this point of failure, they still develop 100% of the tensile strength on direct pull. Assuming a proof strength 85% of tensile, the 80% of proof strength recommended checks exactly with Hill's 68% of tensile, since 80% of 85% is 68%.

Theoretically, a threaded joint should be prestressed to or above the yield point of the weakest material and then slightly loosened. This sets up residual stresses at the points

of greatest stress concentration, such as the roots of threads, and these are beneficial when the joint is subjected to fatigue.

AMOUNT OF TORQUE. Torque, rather than bolt strain or angular movement of a nut or screw head, is commonly used as a means of evaluating the stress induced in the fastener. This is because it lends itself to practical use. In practice the variables of frictional conditions and commercial torque-measuring equipment must be accepted.

For bolts tightened with nuts the formula $PL = RDT$ has been found to be reasonably accurate, where PL = torque, inch-pounds; R = a torque coefficient depending on frictional conditions; D = bolt diameter, inches; and T = tensile load, pounds.

The frictional conditions depend on class of thread, thread fit, size of bearing area of the nut or bolt head, whichever is driven, smoothness of the bearing areas in engagement, frictional characteristics of the materials engaged, the presence and kind of platings or lubricants, temperature, and other factors. For ordinary steel nuts and bolts, driven dry in steel, R approximates 0.2. The column for nuts in Table 51 is calculated on this basis. The foregoing formula may be used to derive torques for sizes outside the scope of the table.

By "driven dry" is meant the use of commercial bolt and nut finishes without actually lubricating the assembly. Some materials, like stainless steel, and some platings, like zinc, tend to increase the coefficient of friction; other materials, like aluminum, and other platings, like cadmium, tend to decrease it.

Even when known, the resultant torque is nominal only, and as much as plus and minus 30% variation has been observed in commercial nut and bolt torques driven under such conditions of uniformity as would be obtained in production use.

When screws are torqued by the head, the additional variables of screw head shape and of the material of the tapped hole complicate the problem of estimating torque.

For cap screw torques the following formulas, used in calculating the last four columns of Table 51, apply:

Hexagon, round, and fillister heads:

$$\frac{PL}{W} = \mu_b R_b + R_t \left(\mu_t \sec \alpha + \frac{1}{2\pi N R_p} \right)$$

For 80-degree countersunk heads:

$$\frac{PL}{W} = 1.524 \mu_b R_b + R_t \left(\mu_t \sec \alpha + \frac{1}{2\pi N R_p} \right)$$

where P = force applied to wrench, pounds
L = effective length of wrench, inches
W = total induced tension force in bolt or screw shank, pounds
μ_b = effective coefficient of friction on bearing face
= 0.15 for a spot-faced steel application without lubrication
R_b = effective radius of action of frictional forces on bearing face of bolt, nut, or screw, inches
$= \frac{2}{3}\frac{R_o^3 - R_i^3}{R_o^2 - R_i^2}$, where R_o = outer and R_i = inner radius
R_t = effective radius of action of frictional forces on thread contact faces, inches (= pitch radius, R_p)
μ_t = effective coefficient of friction on contacting surfaces of thread flanks (assumed equal to μ_b)
α = angle between mating faces of threads and a normal to the thread axis
= 30 degrees
N = number of threads per inch
R_p = pitch radius of threads, inches

For both bolts and cap screws, as an alternative to using Table 51, it is recommended that torque tests be conducted under assembly conditions and drivers set to about 80% of the *lowest* breaking torque found on bolts of minimum tensile strength. This insures adequate prestress but almost entirely eliminates the danger of a partial or complete failure during assembly. Partial failures are particularly dangerous as they cannot be detected.

Torques for some of the most widely used fasteners are shown in Table 51. They are not directly applicable if conditions obtain other than those specified.

Machine Screws. In the numbered sizes of the machine-screw range, variation in the proportion of thread depth to diameter for different sizes greatly affects torque conditions. One authority (Ref. 6) lists torques for machine screws tightened with a nut and no lubrication. In Table 52 these have been converted to the torque necessary to induce a combined tensile stress of 60,000 psi in the screw, and can be applied directly. For example, a 10-24 machine screw of common steel (see Table 50) is rated at 55,000 psi tensile strength. The torque to prestress is therefore ${}^{55}/_{60}$ of the 23.3 in.-lb value listed in Table 52, which is 21.3 in.-lb.

Table 52. Torque to Produce 60,000 psi Maximum Combined Tensile Stress in Machine Screws Tightened with a Nut and No Lubrication

NC Threads				NF Threads			
Size and Pitch	Torque, in.-lb	Size and Pitch	Torque, in.-lb.	Size and Pitch	Torque, in.-lb	Size and Pitch	Torque, in.-lb
		5-40	7.9	0-80	0.8	5-44	8.7
1-64	1.4	6-32	9.1	1-72	1.6	6-40	11.1
2-56	2.3	8-32	17.4	2-64	2.6	8-36	19.0
3-48	3.3	10-24	23.3	3-56	3.7	10-32	29.6
4-40	4.8	12-24	38.9	4-48	5.6	12-28	44.2

As an alternative to Table 52 for machine screws, it is recommended that tests be conducted under actual conditions of assembly and that drivers be set to about 70% of the lowest breaking torque found with screws of minimum strength.

RIVETS AND RIVETED JOINTS

GENERAL CONSIDERATIONS. In making a riveted joint, the head is formed with a set or forming tool, by hand or by hydraulic or pneumatic machines. Machine riveting usually is better than hand work, as the pressure of the machine causes the rivet shank to fill completely the rivet hole. A rivet driven hot shrinks in cooling, pinching the riveted parts and making a firm joint. The cooling also leaves a tensile stress in the rivet, the amount of which cannot be measured. The pinching due to cooling of the rivet causes a frictional resistance between the riveted parts which Stoney found to be about 10,000 psi of rivet area. American and English practice takes no account of this frictional resistance but bases design on the tensile and shearing strength of the plates and rivets. Some French and German authorities base design entirely on the frictional resistance.

6. RIVETS

RIVET HEADS. Rivet heads are of many different forms, the particular form being determined by the use of the joint or fastening. Heads of greatest stiffness and strength are used when the rivet is to resist a tensile stress. Countersunk rivets weaken the plate and should be used only where projecting heads are objectionable.

Large rivets ($^1/_2$ in. nominal diameter and over) are manufactured to proportions given in ASA B18.4-1937. The styles and basic proportions are shown in Fig. 1. Fillet radius under head may be up to $^1/_{16}$ in. For manufacturing tolerances, material specifications, weight, and other details the standard should be consulted. These rivets are designed for use in structural work of bridges, buildings, etc., and in ship and boiler construction. Sizes range from $D = {}^1/_2$ to $1\ {}^3/_4$ in. by $^1/_8$-in. increments.

FIG. 1. Proportions of large rivets ($D = 1/2$ in. and over) after driving. ASA B18.4-1937.

Driven heads, and manufactured heads after driving, have proportions as follows, the notation being the same as in Fig. 1:

Button head: $A = 1.827D$; $H = 0.688D$; $G = 0.954D$.
High button head (acorn): $A = 1.5D + 0.125$; $H = 0.425A$; $F = 1.5H$; $G = 0.425A$.
Cone head: $A = 1.827D$; $B = 0.938D$; $H = 0.828D$.
Pan head: $A = 1.827D$; $B = D$; $H = 0.656D$.

Rivet set and hold-on (dolly bar) impressions for the foregoing rivet heads are as follows, the prime (′) being added to the identifying letter of Fig. 1 to indicate the corresponding impression dimensions:

Button head: $A' = 1.800D$; $H' = 0.641D$; $G' = 0.954D$.
High button head (acorn): $A' = 1.485D + 0.124$; $H' = 0.4A$; $F' = 1.5H$; $G' = 0.425A$.
Cone head: $A' = 1.781D$; $B' = 0.938D$; $H' = 0.781D$.
Pan head: $A' = 1.781D$; $B' = D$; $H' = 0.609D$.

Sharp corners on the exterior of the set or hold-on are rounded to $^1/_{16}$-in. radius.

Boiler Rivets. The rivet proportions after driving, shown in Fig. 2, developed by the Hartford Steam Boiler Inspection and Insurance Co., have been adopted as standard in the ASME Boiler Code, in addition to the ASA standards shown in Fig. 1.

Small rivets ($^7/_{16}$ in. nominal diameter and under) have the proportions indicated in Fig. 3. Fillets under the head may be up to $^1/_{32}$ in. radius, except for countersunk heads. For manufacturing tolerances, materials specifications, weight, and other details, the standard (ASA B18a-1927) should be consulted. Standard sizes range from $D = {}^3/_{32}$ to $^7/_{16}$ in., by increments of $^1/_{32}$ in., omitting $^{13}/_{32}$ in.

2 "	.324	.043	.144	.27	8 "	.504	.067	.224	.44					

* Size No. is the trade name or weight of 1000 rivets. † Body diameter tolerances are: 8 oz–2 1/2 lb, +0.002, −0.004; 3–10 lb, +0.003, −0.006; 12–16 lb, +0.004, −0.008.

Coopers' rivets are illustrated in Fig. 4, the basic dimensions being listed in Table 2.

Belt rivets are similar to the coopers' rivets (Fig. 4), except the proportions are such that circumference A is sharp instead of cylindrical. Dimensions are listed in Table 3.

RIVET HOLES. The rivet holes in a plate may be either punched or drilled. Drilling is preferred as the action of the punch causes an injurious lateral flow of metal. It is current practice to make holes $^1/_{16}$ in. larger than the cold rivet diameter, except that for rivets not over $^7/_8$ in. in diameter a hole of $^1/_{32}$ in. greater diameter than the rivet is preferred. Where work is to be reamed, it is usual to punch the holes $^1/_8$ or $^3/_{16}$ in. less than the finished diameter, and to drill or ream to the proper size after the parts are assembled.

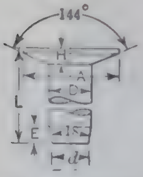

FIG. 4. Proportions of coopers' and belt rivets. See Tables 2 and 3.

It is good practice to remove the sharp corner at both ends of the reamed holes, so that a fillet will form where the body joins the head in finished rivets. Also, annealing will equalize the internal stresses caused by punching, and thus restore the strength of the plate.

The ASME Boiler Code Committee recommends for boiler work that: Rivet holes, except for attaching stays or angle bars to heads, shall be drilled full size with plates, butt-straps, and heads bolted in position; or they may be punched not to exceed $^1/_4$ in. less than full diameter for plates over $^5/_{16}$ in. thick, and $^1/_8$ in. less than full diameter for plates not

PRESSURE REQUIRED TO DRIVE RIVETS. According to Wilfred Lewis, the pressure required to drive a hot rivet is 150,000 psi or 75 tons per square inch of rivet cross-sectional area. For cold riveting, the values are twice as great.

7. RIVETED JOINTS

RIVET SPACING. Rivet spacing has been the subject of much controversy and experiment. The rivets must be spaced far enough apart to allow proper clearance for use of the set during driving; 3/16 in. is the minimum clearance. However, rivets must not be spaced at such a distance that the fastened parts open between rivets, allowing leakage in a fluid pressure joint, or the accumulation of dirt or water to aggravate rusting in a structural joint. With the usual proportions of riveted joints, a distance from the center of the rivet to the edge of the plate equal to (rivet diameter × 1 1/2) is sufficient to prevent tearing or shearing.

ARRANGEMENT OF RIVETS. When several rows of rivets are used in lap joints, the rivets may be arranged as (1) chain riveting; (2) staggered riveting. (Fig. 5.) See Figs. 6 to 12 for examples of the use of the two types in boiler work.

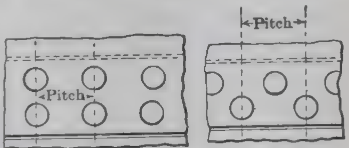

FIG. 5. Chain and staggered riveting.

Boilers and Pressure Vessels. Proper spacing of rivets for joints in boilers and pressure vessels is given in Figs. 6 to 12 and in Tables 5 to 10 of this article.

Structural Joints. According to the specifications of the American Institute of Steel Construction, minimum rivet distances should be as shown in Table 4.

Table 4. Minimum Rivet Distances for Structures

Rivet diameter, in.	1/2	5/8	3/4	7/8	1	1 1/8	1 1/4
Between centers of rivet holes, minimum	1 1/2	1 7/8	2 1/4	2 5/8	3	3 3/8	3 3/4

In rolled edge, sloping flanges *	3/4	7/8	1	1 1/8	1 1/4	1 1/2	1 3/4

* May be decreased 1/8 in. when holes are near end of beam.

Maximum pitch in the line of stress of compression members composed of plates and shapes should not exceed sixteen times the thickness of the thinnest outside plate or shape, or twenty times the thinnest enclosed plate or shape, with a maximum of 12 in. Distance between lines of rivets at right angles to the direction of stress should not exceed thirty times the thickness of the thinnest shape or plate. For angles in built sections with two gage lines, with staggered rivets, the maximum pitch in the line of stress in each gage line should not exceed twenty-four times the thickness of the thinnest plate, with a maximum of 18 in.

Pitch of rivets at the ends of built compression members should not exceed four times the rivet diameter for a length equal to one and one-half times the maximum width of the member. In tension members composed of two angles, a pitch of 42 in. is permissible and

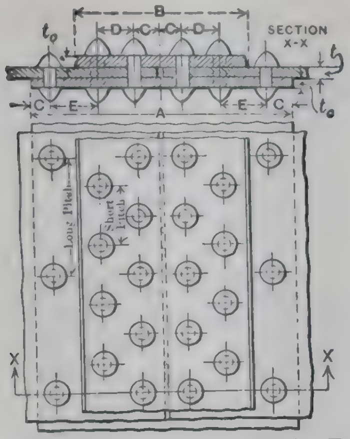

FIG. 11. Triple-riveted butt joint. See Table 7.

Table 7. Dimensions and Efficiency of Triple-riveted Butt Joints

(See Fig. 11)

Joints for plate thicknesses of 3/4 in., and 7/8 to 1 in. (both inclusive) fail by tearing the plate between rivet holes in the second row and shearing a rivet in the outer row. All other joints fail by tearing the plate between rivet holes in the outer row.

in compression members 24 in.; but the ratio l/r for each angle between the rivets should be not more than three-fourths of that for the whole member. Maximum distance from the center of any rivet to the near edge should be twelve times the thickness of the plate but should not exceed 6 in.

STRENGTH AND EFFICIENCY OF RIVETED JOINTS. In calculating the strength of riveted joints the stress conditions which would exist at the yield point are assumed, that is, plastic deformation permits each rivet shearing area to take an equal share of the total load.

Shearing Strength. Total resistance to shearing of the rivets is equal to the number of shearing areas times the cross-sectional area of each rivet, $\pi d^2/4$, times the shearing stress, S_s. ASME boiler code values of S_s are 44,000 psi for steel rivets and 38,000 psi for iron rivets. These are ultimate values; with a factor of safety of 5 the working stresses are 8800 psi and 7600 psi, respectively. For structural rivets the working stresses in shear are 10,000 psi for hand-driven rivets and 13,500 psi for power-driven rivets.

For aluminum rivets, ultimate shearing strengths are: 17S-T, 33,000 psi; 24S-T, 42,000 psi (cold driven); 53S-T, 23,000 psi (cold driven); 53S-W, 18,000 to 24,000 psi (hot driven), depending on temperature. Cold-driven rivets are assumed to have had proper quenching treatment immediately prior to driving.

Crushing Strength. Joint failure may result from crushing between the rivet and the plate. Resistance to crushing at one rivet is equal to the projected bearing area, dt, times the crushing stress, S_c, where t is the least thickness of plate or plates through which the load is transferred to the rivet. ASME boiler code prescribes S_c = 95,000 psi for steel

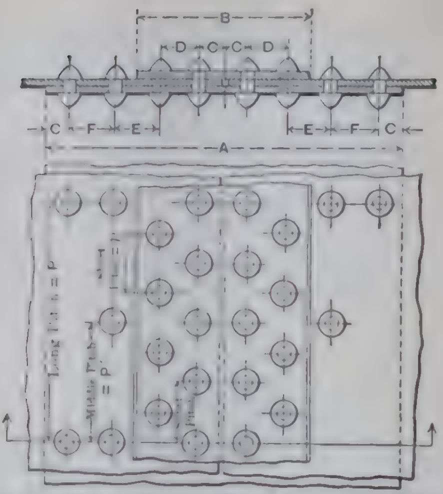

Fig. 12. Quadruple-riveted butt joint. See Table 8.

Table 8. Dimensions and Efficiency of Quadruple-riveted Butt Joints

(See Fig. 12)

Joints for 3/4-in. and 7/8-in. to 1 1/4-in. plates (both inclusive) fail by tearing the plate between rivet holes in the third row and shearing the rivets in the two outer rows. All other joints fail by tearing the plate between rivet holes in the outer row.
